Thermal Conductivity. Measurement of thermal conductivity finds its widest application as an index to the chemical composition of gases. With the exception of heat-insulating materials, it is not an important final property of a product.

Calorific Value. Calorific value is an extremely important property of fuels, of course, and in this connection is measured widely. This property is also used to a limited extent in determining the chemical composition of gases.

Explosibility and Flammability. Explosibility and flammability apply mainly to gases and vapors and are measured, of course, in the interest of safety to personnel and equipment.

Humidity. Generally, humidity is considered a term to signify some function of the concentration of water vapor in air. It is also being applied today to denote the concentration of other vapors in air or in other gases. This is another example of a variable which is not important as a final property of a substance but which is extremely important as a processing condition. It is highly important in comfort and process air conditioning and to such operations as drying, absorption, adsorption, and storing.

Color. Color is of principal importance as a final product quality, although it is used to a limited extent in determining chemical composition. Chlorine and nitrogen dioxide, for example, are gases, the colors of which vary with concentration. Hydrogen sulfide reacts with lead acetate to produce black lead sulfide. By subjecting a lead-acetate-treated paper to hydrogen sulfide gas and measuring the intensity of the black color photoelectrically, an indirect measure of the gas concentration is obtained.

Moisture Content. Moisture content is an important property to materials in production as well as to final products. The moisture content of warp yarn as it emerges from the slasher is very important to the success of the subsequent weaving or knitting process. The moisture content of the paper sheet as it emerges from the dry end of the paper machine is important to subsequent converting and printing operations.

Chemical Composition. Product purity is of especial significance to the chemical, petroleum, and pharmaceutical industries. In many cases, temperature, pressure, and other process variables are measured today as means to control product purity. Advances made in the direct measurement and control of chemical composition over the past few years undoubtedly will have a marked effect upon industrial-instrumentation techniques. Why use the boiling point of a liquid as an index to purity if an equally practical means for directly analyzing the composition of the liquid is available?

BASIC CRITERIA OF MEASUREMENTS

The means for measuring the numerous process variables are about as difficult to classify or group as the variables themselves. Since the process variables are measured and controlled because they change, it follows that some phenomena must be measured which reliably represent these changes. For many measuring instruments, these phenomena fall into one of the following categories: (1) change of pressure and (2) change of electrical voltage, resistance, or current.

The discussion of measuring instruments to follow does not correspond to the conventional manner of presentation followed in most handbooks and texts. Usually each process variable is taken up individually, first exhausting temperature measurement, pressure measurement, and the like. In this discussion, an attempt is made to interlock the major measuring instruments on the basis of the phenomena which they utilize as their bases of measurement. If it is desired first to study all temperature-measuring instruments, then all pressure-measuring instruments, etc., reference to texts listed in the bibliography is suggested.

PRESSURE-ACTUATED INSTRUMENTS

Pressure-actuated instruments are of two general types, *viz.*, (1) those designed to measure pressure as a process variable and (2) those designed to measure pressure as an index of some other process variable, such as temperature, flow, or liquid level. In either case, the measuring means used are strikingly similar.

Elements for Measuring Pressure Changes. Whether a pressure change is due to a change in flow, a change in liquid level, a change in temperature, or a change in process pressure itself, there are seven basic elements which will measure these pressure changes. These are (1) the helix, (2) the spiral, (3) the bellows, (4) the compensated bellows, (5) the bourdon tube, (6) the mechanical manometer, and (7) the electrical manometer (see Fig. 10-1).

The helix, spiral, bellows, and bourdon tube have much in common in that they comprise metal enclosures which expand when exposed to internal pressure. Expansion of the helix, spiral, and bourdon tube causes a twisting action. By attaching a pen or pointer to these elements by means of a link, an indication or record of movement of the element and, consequently, of pressure is obtained. Expansion of a bellows causes a linear movement, but attachment of pen or pointer via links is similar.

In industrial instruments, the manometer generally takes the form of a U tube filled with water, mercury, or other suitable liquid. Pressure is applied to both sides of the manometer and causes a float in one side to rise or fall. This float may be directly connected to a pen or pointer by means of a link, or the float may raise or lower an armature which is part of a solenoid. This latter arrangement permits electrical transmission of the measurement over almost unlimited distances.

Elements for Creating Pressure Changes (see Fig. 10-2). Obviously, where pressure itself is the process variable being measured, the changes in pressure are created

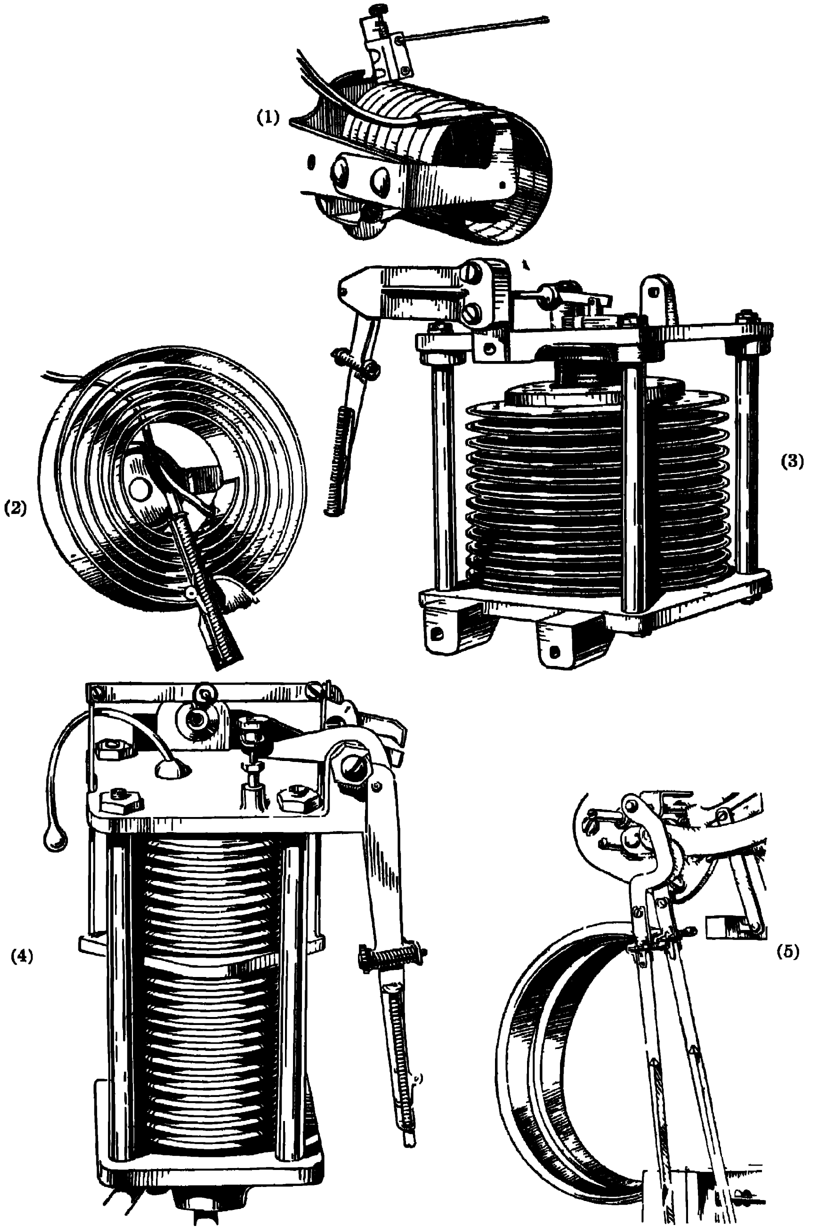

FIG 10-1 (1) Helix used in pressure gauges and pressure-type thermometers (2) Spiral used in pressure gauges and pressure-type thermometers (3) Bellows used in pressure and vacuum gauges and in bubble- or diaphragm-type liquid-level gauges. (4) Bellows with barometric compensation used in absolute pressure gauges. (5) Bourdon tube used in pressure gauges.

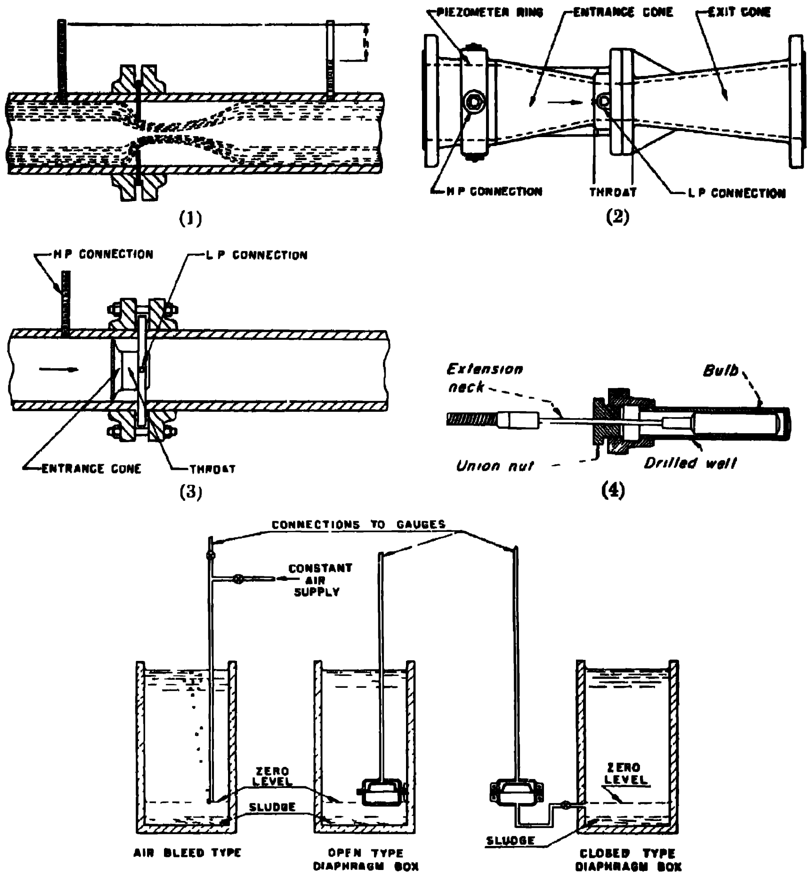
within the process, and all that is required is to connect the pressure-measuring element to the process by means of suitable pipe or tubing.

Pressure changes which correspond to changes in flow rate are created by one of several devices, including (1) orifice, (2) venturi, and (3) flow nozzle. If a restriction is placed in a pipe line containing a flowing fluid, a pressure differential will be created by the restriction. This differential in static pressure bears a definite relationship to the rate of flow past the restriction and, therefore, can be used as a measure of fluid flow. Two pressure taps, one on either side of the restriction, are connected to a manometer.

Pressure changes which correspond to changes in temperature are created by thermometer bulbs (see Fig. 10-2(4)) of three principal types, *viz.*, (1) mercury-filled, (2) gas-filled, and (3) liquid-plus-vapor filled. When any closed vessel is subjected to a rise in temperature, the internal pressure of the vessel will be increased. The opposite action occurs when a fall in temperature is involved. The mercury-filled system comprises a bulb, connecting capillary tubing, and helix or spiral, all filled with mercury. As the bulb, which is located in the medium to be measured, is heated, the mercury expands causing the measuring element to expand. In the gas-filled system, the mercury is replaced with a suitable gas—the principle is exactly the same. In the liquid-plus-vapor system, the bulb is filled with a liquid and its vapor. As the bulb is heated, more of the liquid vaporizes, increasing the internal pressure of the measuring system. Systems of the latter type have the advantage of not being affected by ambient-temperature changes along the capillary connecting tubing.

Pressure changes which correspond to changes in liquid level employ a manometer or bubble pipe. In the manometer system, two taps are made in the side of the vessel containing the liquid. As the liquid level rises or falls with relation to these



(1) (2) (3) (4) (5)

FIG. 10-2. (1) Orifice plate used in differential-pressure-type flow meters. (2) Venturi tube used in differential-pressure-type flow meters. taps, the pressure differential changes. By connecting these taps to a manometer, just as with an orifice-type flowmeter, the position of the manometer float will indicate the level in the vessel. In the bubble-pipe system (see Fig. 10-2(5), an open-ended pipe is placed in the vessel, and air under pressure is forced into the pipe, causing bubbles to emerge from the end of the pipe. By regulating the supply air pressure so that a definite number of bubbles rise from the pipe over a given time and by measuring the back pressure in the system required to maintain this condition, a measure of the head of liquid in a vessel is obtained. The back pressure is measured by means of a spiral or bellows.

ELECTRICALLY ACTUATED INSTRUMENTS

A change in electrical resistance, electromotive force, or current is used to measure any number of the process variables. Some of the more important variables measured in this manner include *temperature* (thermocouple or thermopile), *pressure* (thermocouple, electrical resistance, or ionization), *moisture* (electrical conductivity), *pH* (glass electrode), *liquid level* (electrodes), and *chemical composition* (Geiger counter, dropping mercury electrode, etc.).

Instruments for Measuring Electrical Changes. There are two basic types of instruments for measuring electrical changes, *viz.*, (1) deflectional-type millivoltmeter and (2) null-balance potentiometer (galvanometer and electronic types). Where precision is required, the potentiometer-type instrument generally is used.

Millivoltmeters (see Fig. 10-3) employ the D'Arsonval galvanometer. Deflections are obtained by the reaction between an energized coil and the field of a permanent magnet. The coil of fine wire is connected across the circuit to be measured through spiral springs. It is supported by pivots and free to move in the annular space between a soft-iron core and the pole pieces of a permanent magnet. Owing to the shape of the pole pieces and core, the strength of the magnetic field is uniform. Hence, the deflections of the pointer are directly proportional to the current, and the scale divisions are uniform.

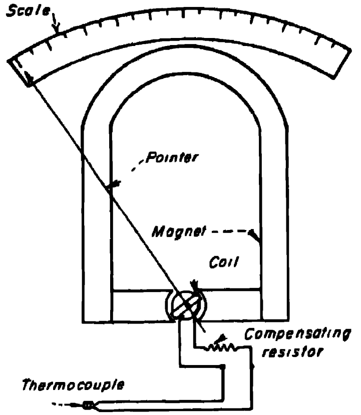

Fig. 10-3. Deflectional-type millivoltmeter.

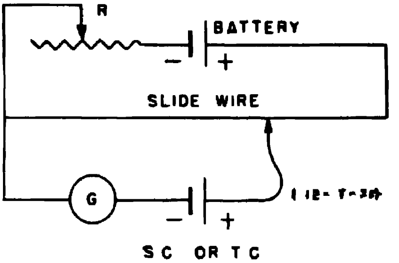

Fig. 10-4. Basic circuit of null-balance-type potentiometer.

Although it is possible to measure the temperature of a thermocouple directly by means of a millivoltmeter, this method introduces as a possible variable the resistance of the leads and various connections. Consequently, a potentiometer is generally used as the measuring circuit in precision instruments, since in this method resistance is ruled out as a variable owing to the fact that the electrical potential applied is balanced against an equal and opposite potential produced by a battery. An elementary potentiometer circuit is shown in Fig. 10-4. In the upper circuit, the battery produces a potential drop in the slide-wire which may be adjusted by resistance *R*. In the lower circuit, an opposite potential is produced by a standard cell of definitely known voltage, and the drop in the slide-wire can be made equal and opposite to that produced by the battery by an adjustment of the slider, this point being indicated by a zero reading of the galvanometer. A thermocouple can then be substituted for the standard cell and the galvanometer again brought to zero by adjusting the slider. The relation between the first and second slider readings is a measure of the difference between the thermocouple potential and that of the standard cell, and the slide-wire positions may be calibrated in terms of the temperatures of the hot junction corresponding to the various potentials. The potentiometer just described is manually balanced. In industrial instruments, the balancing action is accomplished automatically, and the thermocouple voltage (in terms of temperature) is indicated continuously by mechanical, electrical, or electronic means.

The detecting and rebalancing means used in one type of electronic potentiometer are illustrated in Fig. 10-5. Briefly, the d-c millivoltage created by the thermocouple is changed to an a-c voltage of proportional magnitude in a converter. The converter is essentially a flat metal reed oscillating between two contacts connected to the opposite ends of the primary winding of an input transformer. The unbalanced d-c voltage is impressed across the converter and the center tap of the primary winding on the input transformer. As the reed moves from one contact to the other, any unbalanced d-c voltage will cause direct current to flow first in one direction through one-half the primary winding, then in the opposite direction through the other half. This action generates an alternating flux in the input transformer core which, in turn, induces an alternating voltage on the transformer secondary.

The action of the converter is related to the a-c supply voltage by the energizing coil which is excited by the a-c supply voltage through a stepdown transformer. The reed is polarized by a permanent magnet and, therefore, is actuated by the energizing coil to oscillate in synchronism with the a-c supply voltage. The reed closes one contact to the transformer for one-half the supply-voltage cycle and the other contact for the other half, making one complete oscillation for each cycle. The direct current flowing in each half of the transformer primary winding, therefore, will create an alternating voltage in the transformer secondary of the same frequency as the supply voltage. This alternating voltage is amplified in voltage and power to where it will actuate a two-phase balancing motor.

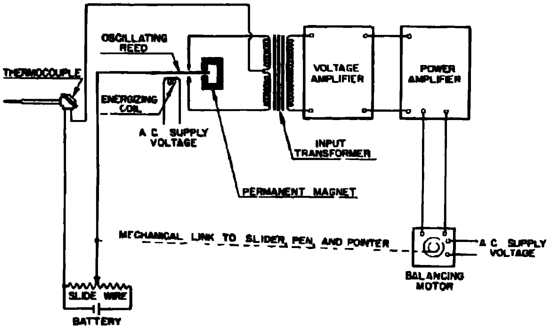

FIG. 10-5. Schematic diagram of electronic-type potentiometer.

If there is an unbalance between the slide-wire voltage and the thermocouple voltage, the balancing motor functions to rebalance the two voltages by moving the slider on the slide-wire. The direction in which the motor turns is determined by a definite phase relationship between the a-c supply voltage and the amplified a-c thermocouple voltage. This relationship depends, of course, upon whether the measured variable is increasing or decreasing in magnitude. The use of electronic and electromechanical components in this potentiometer has virtually eliminated the multiplicity of moving mechanical parts common to previous mechanically balanced potentiometers.

Elements for Creating Electrical Changes. In the foregoing description of the millivoltmeter and potentiometer, the thermocouple was used as the detecting means. This was done merely for convenience. Instruments of the type just described can be used to measure electrical changes produced by other devices such as pH electrodes, resistance thermometers, tachometer generators, and others.

Temperature-measuring Devices—Thermocouple. The thermocouple (see Fig. 10-6) consists of two dissimilar metal wires joined at one end, generally known as the hot junction. Often the wires are contained in tubes for protection against excessively oxidizing or reducing furnace atmospheres and from other types of corrosion. When a thermocouple is heated at one end (hot junction), while the free ends (terminals) are kept at a known temperature, a potential is set up between the terminals which is related to the hot-junction temperature. This potential can be measured by a millivoltmeter or potentiometer, the latter instruments being calibrated in terms of temperature.

As will be pointed out later, thermocouples not only are used in the direct measurement of temperature but are also used in instruments for measuring high vacuums, in spectrometers for measuring chemical composition, etc. The most commonly used combinations of wire include platinum and platinum–10 per cent rhodium, iron-constantan, chromel-alumel (Hoskins), and copper-constantan. Temperature-millivolt equivalents for these couples can be obtained from any instrument manufacturer specializing in pyrometry.

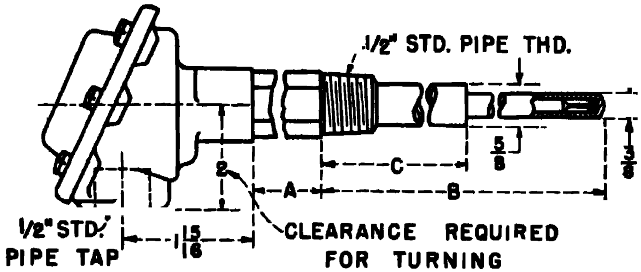

Fig 10-6 Typical thermocouple and protecting tube. Hot junction is shown inside tip at right, head with terminals for connecting extension lead wire is at left.

Thermopile. To increase the sensitivity and the emf output of a thermocouple, several thermocouples can be connected in series to form a thermopile, as illustrated in Fig 10-7. These devices are used widely in radiation pyrometers, which focus energy from a furnace or other hot object onto the thermopile by a lens system. Thus, the temperature-detecting device does not have to contact directly the object of measurement but can be located several feet away.

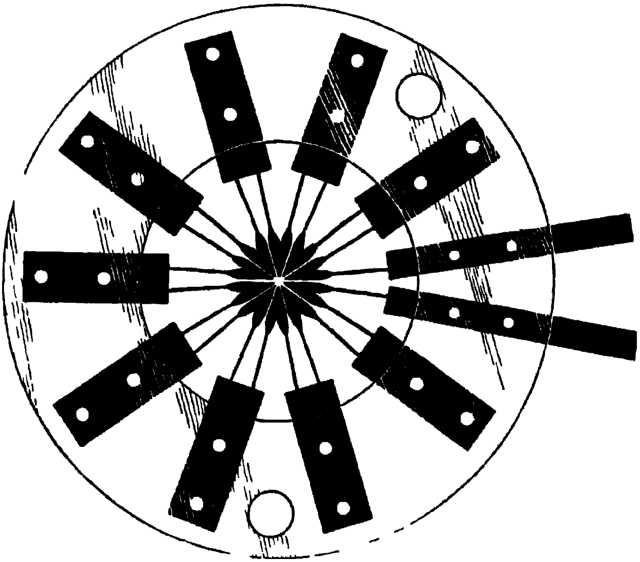

Fig 10-7 Enlarged view of thermopile (group of thermocouples connected in series) used in radiation-type pyrometer.

Resistance Thermometers. The electrical resistance of metal wire, usually a coil of nickel or platinum, is the temperature-sensing device employed in resistance thermometers. Since there is a definite relation between temperature and the resistance of the wire, the electrical resistivity of the wire can be measured and indicated or recorded in terms of temperature.

Electrometric pH Measurement. In electronic pH measurement, two electrodes are immersed in the unknown solution. One electrode, the *measuring* electrode, is sensitive to the presence of hydrogen ions; the other electrode, the *reference* electrode, is required to complete an electric circuit through the solution and to supply a constant potential. The reference electrode is not affected by pH. Since to date it is impossible to measure the potential of a single electrode, the reference electrode must be used. Each electrode is sometimes referred to as a *half cell.* The potential measured is the algebraic sum of the two electrodes and is conveniently measurable with a potentiometer.

Measuring Electrodes. Four outstanding electrodes have been developed which are sensitive to pH, *viz.*, (1) the hydrogen electrode, (2) the quinhydrone electrode, (3) the antimony electrode, and (4) the glass electrode. The glass electrode is the modern and most practical means of pH measurement and has practically replaced the other electrodes for industrial application.

Glass Electrode. When a thin membrane of special glass separates two solutions of different hydrogen-ion concentrations, a potential is created which is a function of the two concentrations. If the pH of one solution is maintained constant, that of the other solution can be determined from the potential produced. A typical glass electrode consists of a glass tube about one-half inch in diameter with a bulbous glass tip. The solution of constant pH is contained inside the tip. Several theories regarding the operation of glass electrodes have been advanced, but their explanation must be left to complete texts on the subject.

Reference Electrodes. A good reference electrode must possess a reasonably constant potential regardless of temperature changes, must maintain this potential over long periods of time, must not easily be poisoned by solutions, must be simple and easy to maintain, and must not in itself be affected by change in pH. Years of experience have proved the calomel electrode, saturated or unsaturated, to be the best answer to the above requirements. The saturated calomel electrode, most widely used, comprises mercury and mercurous chloride (calomel) with saturated potassium chloride as an electrolyte. In a typical electrode, a liquid junction between the electrode and the process solution is established by means of a small hole covered by a ground-glass sleeve. Diffusion of electrolyte from the electrode to the solution is slow but sufficient to provide excellent electrical conductivity.

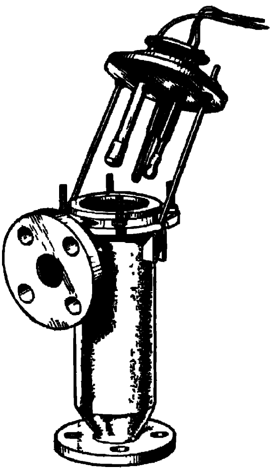

FIG. 10-8. pH electrode assembly designed for installation in pipe lines. (*National Technical Laboratories.*)

Electrode Assemblies. Sturdy construction of electrode assemblies has been responsible for a wider industrial use of pH measurement during the past few years. The flow assembly illustrated in Fig. 10-8 can be installed directly in process pipe lines and is capable of operating under moderate pressures. Numerous materials of construction, including porcelain-covered iron, rubber, stainless steel, nickel alloys, and glass, are available. An assembly available for immersion in tanks, vats, and other process vessels also is available.

pH Recording and Controlling Equipment. Null-balance potentiometers rather than deflectional instruments are required for pH measurement since the measuring instrument must not draw any appreciable current from the electrodes. Any current flow would cause polarization at the electrodes, immediately upsetting the accuracy of measurement. Potentiometers are available in four basic ranges: 0 to 7, 3 to 10, 6 to 13, and 2 to 12 pH. Pneumatic and electrical control components available with thermocouple potentiometers are also available with pH potentiometers.

Oxidation-reduction Potential. The measurement of oxidation-reduction potential is a reasonably well-known technique of physical chemistry. However, its application to industrial processes is just emerging from the experimental stage. Basically, oxidation-reduction potential is to oxidation and reduction chemistry what pH is to double-decomposition chemistry or neutralization of acids and bases. Kolthoff and Furman state that "It is the potential an unattackable metal electrode assumes in a solution relative to that of the normal hydrogen electrode." The measurement of oxidation-reduction potential in practice involves the use of a standard reference electrode, such as a calomel electrode, and a platinum, gold, or other nonattackable metallic electrode. The potential from the electrodes is measured by an instrument quite comparable to a potentiometer designed for pH measurement, but with the scale graduated to read in millivolts rather than in pH units. The measured potential may be expressed as millivolts or as E_h or R_h.

Because oxidation-reduction-potential measurement has been so infrequently used, it is a fertile field for investigation. In addition to concentration control of reducing and oxidizing solutions, it has been used to measure the chlorine content of water to less than one part per million, using a calomel and a silver–silver chloride electrode. Chemical engineers will immediately visualize many other applications which can be corroborated only by test data. Much can be expected from oxidation-reduction-potential measurements within the next few years.

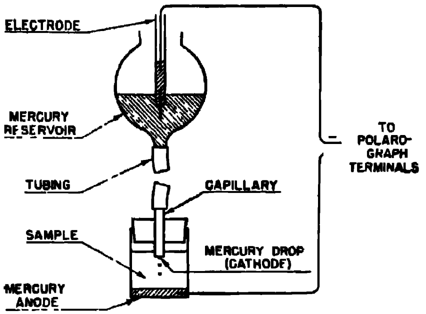

Fig. 10-9. Dropping mercury electrode used in polarograph. (*E. H. Sargent & Co.*)

Dropping Mercury Electrode. The polarograph (employing the dropping mercury electrode) is an analytical instrument, both qualitative and quantitative, for determining the chemical constituents of either aqueous or nonaqueous solutions. Although extremely small quantities of material can be detected, it is not limited to microanalysis. Both in micro- and macroanalytical work, it replaces tedious and slow wet-chemical methods for determining metallic and organic constituents.

The dropping mercury electrode, illustrated schematically in Fig. 10-9, comprises a very fine bore capillary tube connected by a flexible tube to a mercury reservoir and placed in the solution so that very fine drops of mercury are formed beneath the surface. The rate of mercury flow can be adjusted by varying the height of the reservoir and normally amounts to a drop every one to three seconds. The mercury reservoir is connected to one terminal of the polarograph; the other cell terminal is a pool of mercury in the bottom of the solution vessel.

In operation, a few drops of mercury added to the sample act as one electrode of the cell. The dropping mercury electrode next is inserted. An inert gas, usually nitrogen, then is bubbled through the solution to remove atmospheric oxygen which is reducible and gives a polarographic wave not usually of interest to the analyst. As the voltage impressed on the cell is raised slowly, the current remains nearly constant until a voltage is reached at which a component of the solution is reducible. The current then rises sharply to a new level at which it remains constant until the voltage is reached at which a second component is reducible. Another sharp rise in current to a new constant value then occurs. These sharp rises in current are referred to as polarographic steps or waves. Since the polarographic steps for various components occur at different voltages, several substances can be determined in one solution on a single polarogram.

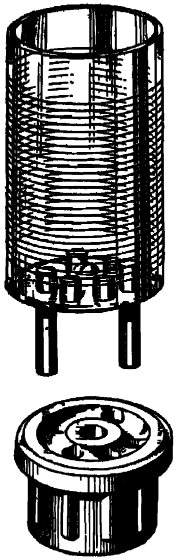

FIG. 10-10. Electrical humidity-sensing element. (*American Instrument Co.*)

The output from the polarographic cell is fed to the recorder so that the displacement of the pen from zero is determined by the amount of current flowing through the cell. The chart is driven by a constant-speed synchronous motor. The polarographic bridge which supplies voltage to the cell is also driven by a synchronous motor so that the chart displacement is a linear function of the voltage applied to the cell, *e.g.* the time ordinate of the chart becomes, in essence, the voltage ordinate. The record obtained, therefore, is current vs. voltage.

Electric Humidity Measurement. A comparatively new development in hygroscopic measurement is illustrated in Fig. 10-10. Here a double coil of palladium wire is wound on an insulating core, the wires being coated with a film of hygroscopic lithium chloride suspended in a water-soluble coating. The electrical conductivity of the coating varies with the relative humidity and is measured by a microammeter provided with a-c energy through a transformer and a full-wave copper-oxide rectifier. To secure a long range, several such sensitive elements must be used in series, each different in over-all resistance from the others. One instrument of this type is available with electronic recorders and electric or pneumatic control.

Electronic Dew-point Recorder. Referring to Fig. 10-11, which is a schematic diagram of one type of automatic dew-point recorder, note that the gas under test enters the gas chamber where it comes in contact with a thin metallic mirror to which a thermocouple is attached. The mirror is refrigerated to −90°F. Consequently, moisture from the gas under test forms on the surface, thus fogging the mirror. Coincident with the formation of fog or dew, the mirror is heated to the temperature at which the dew vanishes This temperature is the dew point of the gas under test. The electronically controlled heater maintains the mirror at this temperature until the dew point of the gas under test changes, at which time the mirror

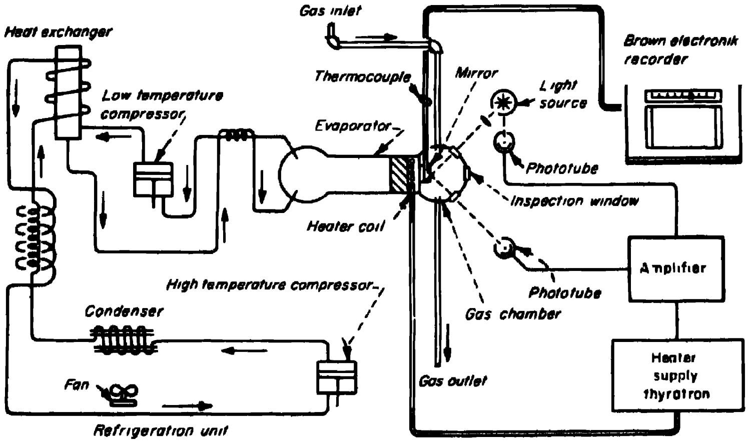

FIG. 10-11. Schematic diagram of dew-point-measuring and -recording system. (*General Electric Co.*)

temperature is changed to coincide with the formation of dew and is held at this new temperature. By recording the output voltage from the thermocouple attached to the mirror by means of a potentiometer, a continuous record of the dew point of the gas is obtained.

In operation, the mirror is constantly refrigerated by a gas flow against the back of the mirror. The refrigerating gas flow is cooled to −90°F by the action of a two-stage compressor and a dual refrigerating system. A heater mounted directly behind the mirror is capable of raising the temperature of the mirror from −90°F to ambient against the opposing cooling effect caused by the refrigerating system. An automatic optical system views the mirror surface and operates by means of a beam of light which passes through one of the windows of the gas chamber and is reflected from the mirror through the other window to the phototube. As the test gas passes through the gas chamber and dew condenses on the mirror, the reflectivity of the mirror lowers, thus decreasing the amount of light reaching the phototube and initiating a change in the magnitude of the heater current.

To reduce the effect of voltage variations and aging on the phototube characteristics, the lamp also shines on a second phototube which is balanced in the electrical circuit against the first tube. The amplified difference between the two phototube currents controls the heater current.

Measuring Moisture Content by Electrical Conductivity. Moisture content of solids can be measured in various ways in addition to the fundamental method of weighing and drying. Probably the commonest method is to measure the electrical conductivity. In the case of crystals or powdered materials it is necessary to ensure a standard density of material before making the measurement. Measuring the humidity of air in contact with the substance is another useful method.

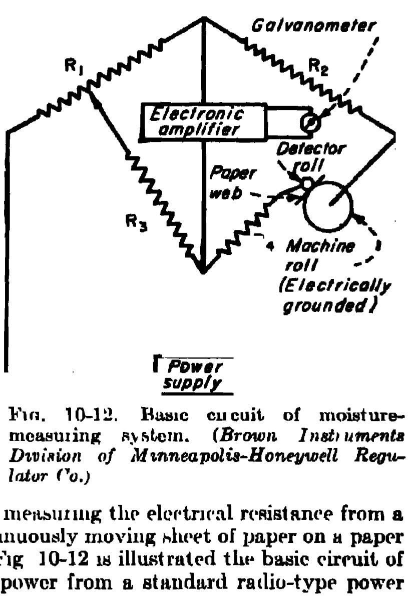

FIG. 10-12. Basic circuit of moisture-measuring system. (*Brown Instruments Division of Minneapolis-Honeywell Regulator Co.*)

In one method, moisture is detected by measuring the electrical resistance from a detector roll in direct contact with the continuously moving sheet of paper on a paper machine or warp on a textile slasher. In Fig 10-12 is illustrated the basic circuit of this device. The bridge is supplied with power from a standard radio-type power supply consisting of a transformer, rectifier tube, and filter.

The bridge consists of resistors R_1, R_2, R_3, and R_4 and the resistance of the object of measurement, which is in series with R_4. R_1 is the slide-wire in the instrument. This resistor is automatically adjusted by the mechanical linkage of the recorder, which, in turn, is positioned by the galvanometer, thus keeping the bridge in balance for changing values in resistance of the unknown. Resistor R_4 is used principally to control the scale shape and because of its extremely high resistance excludes any possible danger to personnel coming in contact with the detector roll.

Inasmuch as the resistances being measured are extremely high, the current in the bridge is extremely low with the safe voltages used. Therefore, it would require a most sensitive galvanometer of the laboratory type to detect small unbalances. It is necessary, therefore, electronically to amplify the unbalances occurring before feeding them into a standard commercial galvanometer. The amplifier consists simply of a twin-triode tube used in a balanced circuit in which the bridge current is fed into the grids, and the galvanometer is placed across the plates. When the grid voltages are at the same potential, the plate currents are equal, and the galvanometer does not deflect. As soon as any unbalance occurs in the bridge, the grid potentials change which, in turn, changes the plate currents, causing the galvanometer to deflect.

X-ray Diffraction Spectrometer. The use of X-ray diffraction for analytical purposes has become an extremely important aid to several of the process industries. The time and technique required to conduct an analysis by this method through photographic means have formerly limited its usefulness. However, development of the Geiger-counter X-ray spectrometer, together with the high-speed recording potentiometer, has greatly simplified the procedure and reduced the time required to make an analysis.

Basically, the diffraction of X rays in a solid serves to analyze its structure. The arrangement of atoms within the solid and their interrelationship provide the analytical information necessary to evaluate such properties as simple chemical identity, particle size and distribution, grain size, and similar properties. In such processes as the following, analysis by X-ray diffraction serves (1) to control addition of dyes, fillers, and accelerators to the rubber batch in the rubber industry; (2) to select the required manganese dioxide ores in battery manufacture; (3) to select clay of proper particle size in the manufacture of high-frequency insulators; and (4) to control the activator in fluorescent materials used in lamps and cathode-ray-tube screens. These applications are representative of a host of others. At present, a tool of the product-development and process-control laboratory, future research may adapt it to continuous process control.

Principle of X-ray Diffraction. When a beam of X rays is directed into a sample undergoing analysis, a series of secondary beams is reflected from the specimen in the form of a diffraction cone. Analysis of this cone with properly sensitized photographic film shows a series of diffraction lines in the form of concentric circles. These lines occur as a result of the cancellation and reinforcement of the reflections from the various atomic planes of the specimen. No two different materials have been found which show identical patterns, and, hence, identification by this means is positive. However, identification by the examination of photographic film is somewhat inadequate.

The use of the Geiger-Muller counter tube in place of photographic film eliminates these inadequacies, making possible an accurate, automatic, relatively fast recording device. The Geiger-Muller tube actually counts quanta of X-ray energy reflected from the specimen. The tube is an adaptation of the type used for cosmic-ray investigations but differs in that it is much more sensitive in the X-ray range and actually produces one count for almost every X-ray quantum entering the tube.

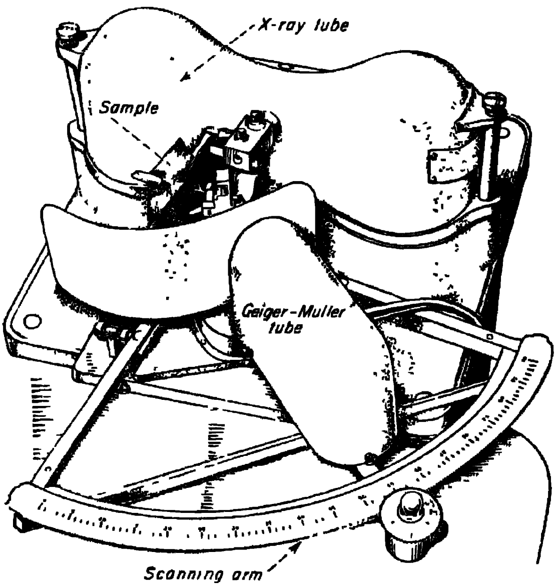
The Geiger-Muller tube comprises a sealed tube filled with an ionizable gas Radiation traveling through the gas within the tube results in partial ionization of the gas which, in turn, allows an electric current to flow through the tube. This current is amplified and put through an electronic integrating circuit so that it can be evaluated in terms of the intensity of X-radiation.

In order to obtain a diffraction pattern with the counter tube, it is necessary to scan a cross section of the diffraction cone. This is accomplished by rotating the counter tube and the sample in such a manner that the former moves at twice the angular speed of the latter so that the tube will be progressively exposed to the various beams which are reflected from the sample. As illustrated in Fig. 10-13, the counter tube is rotated through 90 deg of arc by means of a motor-driven, calibrated scanning arm (goniometer) whose speed of rotation is precisely coordinated with the chart speed of a recording potentiometer. In this way, an exact space relationship between the representative peaks and dips of reflected radiation is reproduced on the recorder chart.

Ultraviolet Spectrometer. Continuous, automatic analysis of a flowing gas or liquid now is possible with the ultraviolet spectrometer and is accomplished by recording the per cent transmission of light through the sample at the frequency selected. Major components of the instrument include a suitable light source, a monochromator, and a measuring system. Automatic analyses of more than one sample flow can be effected by means of electric time-cycle control and associated solenoid valves and fittings in the sample lines.

A tungsten lamp is used to supply light at wave lengths of from 320 to 1,000 millimicrons, while a hydrogen-discharge lamp is used to supply ultraviolet radiation from

220 to 350 millimicrons. Which lamp is used is determined solely by the wave-length-absorption characteristics of the sample under analysis. The monochromator fundamentally is an optical system serving to isolate the wave length necessary to the analysis of the sample. Light from the selected source is focused by an optical arrangement in the lamp housing so that a crescent-shaped image is projected through an aperture and into the separately housed monochromator unit. By means of adjustable slits, the desired wave lengths within the beam of light which enters the monochromator are segregated and directed through the sample cell and thence to the measuring system. The monochromator is provided with a sensitivity and a wave-length control. Light passing through the sample is intercepted by the measuring cell which comprises a phototube whose electrical characteristics are sensitive to changes in light intensity at wave lengths of the transmitted light. The phototube and its associated amplifier develop an output voltage whose value is fixed by the intensity of the light received by the phototube. By measuring and recording this voltage with a potentiometer, the per cent transmission of light through the sample is directly indicated and recorded. Potentiometers for such use generally are calibrated in per cent transmission.



Partial view of X-ray spectrometer, showing X-ray tube, sample location, Geiger-Muller tube, and scanning arm (*North American Philips Co., Inc.*)

The ultraviolet spectrometer is designed principally for recording variations in per cent transmission at a fixed wave length rather than for scanning a spectral region to record absorption spectra. Thus, the instrument can be adjusted to record continuously per cent transmission at a wave length which indicates the purity of a substance. Indications of less than 100 per cent will be produced when the substance absorbs some of the radiation; indications of 0 per cent will be produced when the substance absorbs all the radiation. Since potentiometers suitable to these measurements are available with pneumatic or electric automatic-control components, the possibilities of automatic process-stream purity control are obvious.

Infrared Spectrometer. The most important prerequisite of an infrared spectrometer is a suitable source of infrared radiation. Its final function is to measure the intensity, at various wave lengths, of a beam of such radiation which has passed through the substance under test. Before measurements of the intensity at various wave lengths can be made, the infrared beam which has been passed through the test substance must be broken up into different wave lengths and arranged in numerical sequence. This is accomplished in a fashion similar to that just described in connection with the ultraviolet spectrometer. Since infrared waves are invisible, measurement of their intensity can best be accomplished by measuring their heating effect. By measuring this effect at each wave length, the absorption pattern of the substance under test can be ascertained.

Figure 10-14 shows schematically the path of infrared radiation. Note that radiation from the Nernst glower which constitutes the source *A* of this radiation passes through a rotating shutter *B*, thence through a rock-salt window *C*, and to a condensing mirror *D*. The condensing mirror forms an image of the source in the focal plane of the concave rock-salt lens *E*. The collimated beam passes through the shutter *F* and the liquid cell compartment *G* to a lens *H* which converges the beam through the gas cell or sample compartment *I* and the lens *J* to the upper entrance slit *K* where an image of the source is formed. Radiation from the slit is collimated by a spherical mirror *L* and dispersed by the prism *M*. The desired wave length of the dispersed radiation is reflected from the Littrow mirror *N* back through the prism *M* to the collimator *L*. The collimator focuses on the plane of the exit slit (which lies just below the entrance slit), and the plane mirror *O* reflects the beam against the condensing mirror *P* which focuses an image of the exit slit on the energy receiver *Q* where the heating effect of the wave length, which is selected in accordance with the position of the Littrow mirror *N*, is measured by means of a thermocouple located in the energy receiver. By rotating the Littrow mirror, different wave lengths of the dispersed beam are directed to the energy receiver where their intensity is measured by the thermocouple and recorded by a potentiometer. Thus, a record of the absorption pattern of the substance under test is obtained.

AUTOMATIC PROCESS CONTROL

Despite the fact that automatic process control involves the use of highly technical and often complex mechanisms, the *application* of instruments and automatic controls to an industrial process has only relatively recently graduated from an art to a science. Even today, the science has not been sufficiently simplified and condensed to the point where the average engineer can apply instruments to certain types of process without utilizing cut-and-try methods. Fortunately, during the past few years, a few valuable textbooks on instrumentation have appeared; hundreds of fine technical articles on the subject have been written, a society devoted solely to instrumentation has been organized on a national scale; and, of utmost importance, the ASME has compiled a long list of well-classified instrument terms and definitions. Progress thus is being made and undoubtedly will continue at an even more rapid pace.

Considerable chaos was in evidence in the field of instrumentation before the adoption of a consistent nomenclature. There were as many definitions for a control term as there were manufacturers of such controls. Wherever possible, the new nomenclature is used throughout this section. Unfortunately, many automatic-control terms are somewhat complex and, to the uninitiated, often quite difficult to comprehend. To aid the plant engineer who has had little contact with the new terms, the most important and basic of the ASME definitions are illustrated diagrammatically. In some cases, the definitions appear wordy and cumbersome to handle, but a further analysis will prove that oversimplification would not be wise in these early stages in the development of a nomenclature.

Most of the following sections on terminology are taken from "Graphical Representation and Analysis of Automatic Control Terminology" by J. G. Horn, Development Engineer, Brown Instruments Division, Minneapolis-Honeywell Regulator Co., Philadelphia, Pennsylvania, and were presented at the September, 1946, meeting of ASME in Pittsburgh.

Elements of the Automatically Controlled Process. A certain number of minimum separate elements are required to control a process automatically. These elements are defined (ASME) as follows:

101 An *automatic controller* is a mechanism which measures the value of a variable quantity or condition and operates to correct or limit deviation of this measured value from a selected reference. It includes both the measuring means and the controlling means. (*Automatic regulator* is a synonymous term.)

301 A *process* comprises the collective functions performed in and by the equipment in which a variable is to be controlled.

303 The *controlled variable* is that quantity or condition which is measured and controlled.

304 The *controlled medium* is that process energy, or material in which a variable is controlled.

305 The *manipulated variable* is that quantity or condition which is varied by the automatic controller so as to affect the value of the controlled variable.

306 The *control agent* is that process energy, or material of which the manipulated variable is a condition or characteristic.

The automatic controller comprises the measuring means and the controlling means as shown in Fig. 10-15, illustrating a fluid-heat-exchange process with automatic temperature control. The measuring means may consist of a potentiometer pyrometer system measuring the temperature of the controlled medium, which is a fluid leaving the process. The controlling means consists of a mechanism embodying predetermined controller action affecting the condition or characteristic of the control agent, which is a fluid entering the process. This action upon the control agent produces an effect which corrects or limits the temperature of the controlled medium.

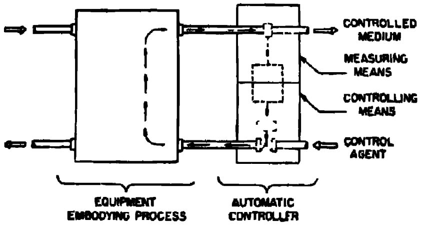

FIG. 10-15. Schematic diagram of process and automatic controller.

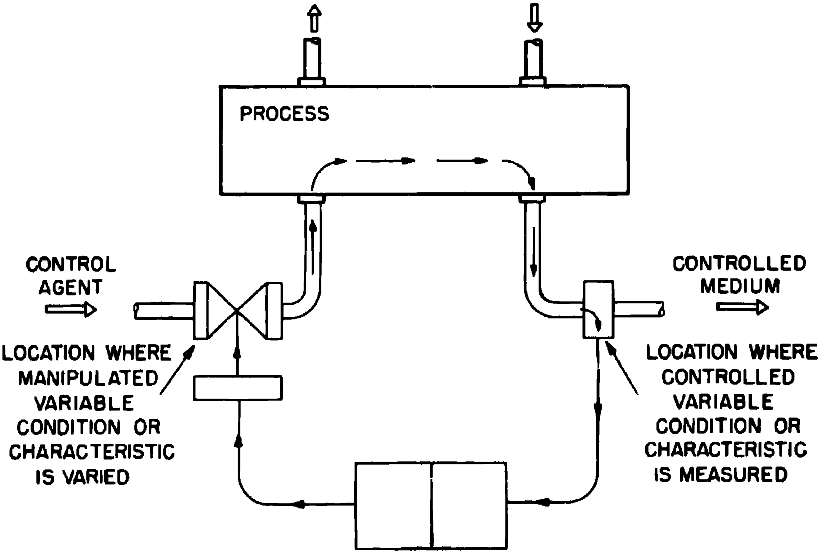
The process equipment and the automatic controller are installed in such a manner that the initial action within the process and the counter action of the automatic controller form a closed loop or circuit of action. The term "equipment" as embodied in this definition does not include automatic-control equipment.

The process is an operation or series of operations in which the value of a quantity or condition is controlled. It includes all functions which directly or indirectly affect the value of the controlled variable.

Figure 10-16 illustrates the same fluid-heat exchanger shown in Fig. 10-15, with additional detail of the process elements pertinent to automatic control. The controlled variable (temperature) of the controlled medium (fluid leaving the process) is measured by the automatic controller which acts in a predetermined manner to vary the value of the manipulated variable (flow) of the control agent (fluid entering the process). The action of the automatic controller restores, or tends to restore, the value of the controlled variable to the desired value.

The controlled variable is a condition or characteristic of the controlled medium. The manipulated variable is a condition or characteristic of the control agent.

Process Characteristics. All industrial processes possess characteristics which determine to a large degree how easily automatic control can be applied and the results obtained from automatic control. If all processes were alike, automatic controllers of one design or one mode would suffice. Unfortunately, processes vary widely in the number of characteristics which they possess and the extent to which these characteristics are manifest. Some of the basic characteristics of a process are defined (ASME) below:



PROCESS
CONTROL AGENT
CONTROLLED MEDIUM
LOCATION WHERE MANIPULATED VARIABLE CONDITION OR CHARACTERISTIC IS VARIED
LOCATION WHERE CONTROLLED VARIABLE CONDITION OR CHARACTERISTIC IS MEASURED

FIG. 10-16. Schematic diagram showing relationship of process elements.

201 *Capacity* is a measure of the maximum quantity of energy or material which can be stored. It is measured in units of quantity.

202 *Capacitance* is the change in quantity contained per unit of change in some reference variable. It is measured in units of quantity divided by the reference variables.

203 *Resistance* is opposition to flow. It is measured in units of potential change required to produce unit change in flow.

204 *Dead time* is any definite delay period between two related actions. It is measured in units of time.

302 *Self-regulation* is a sustained reaction inherent in the process which assists or opposes the establishment of equilibrium.

Various forms of the term "lag" are commonly used to express the delaying or retarding effect inherent in the dynamic characteristics of a controlled system. The characteristics involved in this effect are capacitance, resistance, and dead time, which may exist separately or in combination. These three terms cover the basic concepts involved and, in the interest of clarity, should be used in place of the less exact term "lag."

The type of capacity is determined by the energy or material contained. Likewise the type of capacitance is determined both by the type of quantity contained and by the type of reference variable. Several types of capacity and capacitance may exist together in one process.

A comparison of capacity and capacitance is illustrated in Fig. 10-17. In this example, the capacities are equal, the capacitances are unequal, and the liquid-level surface areas do not vary with change in liquid head. The capacity or "static quantity" is the cubic volume of liquid contained in each vessel. The volume capacitance or "dynamic quantity" is equivalent to the liquid-level surface area of each vessel.

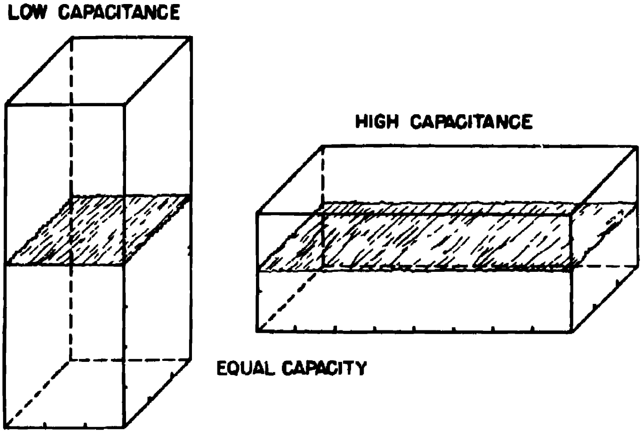


FIG. 10-17 Relationship of liquid volume capacity to volume capacity.

In this example, the capacitance is equal to the change of volume capacity divided by the change of reference variable, the liquid head.

If the shape of the vessel causes the liquid-level surface area to vary with change in liquid head, the capacitance will likewise vary with head. Vessels of different shape have equal capacities if the quantities of material contained are equal. Vessels of different shape have equal volume capacitances if the liquid-level surface areas are equal.

Another comparison between capacity and capacitance is exemplified in a compressed-air tank. The weight capacity at a stated pressure is the weight of air within

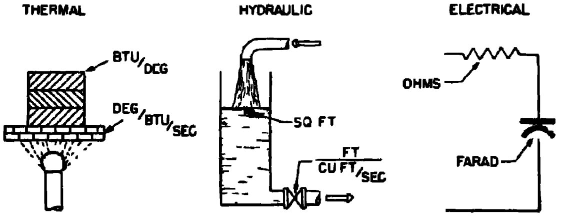

FIG. 10-18. Resistance-capacitance analogies.

the tank at that pressure. The weight capacitance with respect to pressure is the change in contained weight of air divided by the corresponding change in pressure of the tank.

Combinations of resistances and capacitances are frequently found in many industrial processes. Figure 10-18 illustrates single resistance-capacitance analogies for thermal, hydraulic, and electrical circuits.

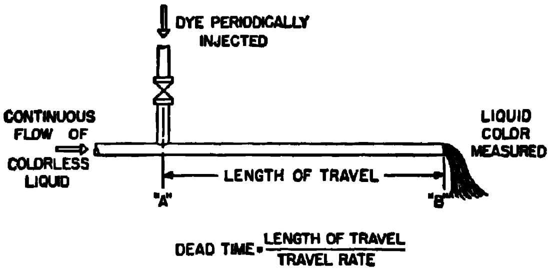
Thermal resistance is measured in degrees per Btu per second. It is equal to the reciprocal of thermal conductance. Thermal capacitance is measured in Btu per degree and is equal to the specific heat (Btu per degree per pound) times the mass (pound).

The hydraulic resistance illustrated is measured in feet of liquid head per unit volume or mass flow of liquid from the vessel. The hydraulic capacitance is measured in square feet of liquid-level surface or pounds of total liquid per foot of liquid head.

The electrical resistance is the voltage per unit ampere or ohm. The electrical capacitance is the farad.

Frequently, the resistance is not a linear quantity, since different values of resistance may be obtained for different values of potential. Likewise, the capacitance may not be a linear quantity with changes in reference variable. Therefore, the value of the capacitance should be based on a definite value of reference variable

The dimensional units of the basic characteristics for several types of processes are summarized in Table 10-1. In this tabulation, capacity represents a static quantity, capacitance, a dynamic quantity. The potential represents a condition at a point in the process which determines the energy at the point. Resistance is the potential per unit flow The controlled variable of the process may be the potential, capacity, or other condition of the process.



DYE PERIODICALLY INJECTED
CONTINUOUS FLOW OF COLORLESS LIQUID
LIQUID COLOR MEASURED
LENGTH OF TRAVEL
"A"
"B"
DEAD TIME = LENGTH OF TRAVEL / TRAVEL RATE

Fig. 10-19. Schematic diagram showing effect of dead time.

Dead time is illustrated in Fig. 10-19 by the use of a fluid-flow process. A small amount of dye is injected periodically at point *A* into a continuously flowing colorless liquid. The liquid mixture flows through a long length of pipe to point *B* before its color is detected The dead time is the time required for the dye to travel from *A* to *B* and is equal to the length of travel divided by the travel rate Point *A* may correspond to the location within a process where a variable change is initiated, and point *B* may correspond to the point at which the variable is measured. In this example, the measuring element does not respond to variable change during the dead-time period of the process

Table 10-1. Units of Measurement of Basic Process Characteristics

Units of	Thermal	Pressure	Liquid level	Electrical
Capacity	Btu	Cubic foot	Cubic foot-pounds	Coulomb
Potential	Degree	Lb psi	Foot	Volt
Capacitance	$\frac{\text{Btu}}{\text{Deg}}$	$\frac{\text{Cu ft}}{\text{Psi}}$	$\frac{\text{Cu ft}}{\text{Ft}}$ or $\frac{\text{Lb}}{\text{Ft}}$	$\frac{\text{Coulomb}}{\text{Volt}}$ = farad
Resistance	Deg/Btu/sec	$\frac{\text{Psi}}{\text{Cu ft/sec}}$	$\frac{\text{Feet}}{\text{Cu ft/sec}}$ or $\frac{\text{Feet}}{\text{Lb/sec}}$	$\frac{\text{Volt}}{\text{Coulomb/sec}}$ = ohms

Elements of Automatic Controllers. The fluid-heat-exchange process illustrated in Fig. 10-20 illustrates the basic elements of an automatic controller. These elements are defined (ASME) as follows:

701 The *measuring means* consists of those elements of an automatic controller which are involved in ascertaining and communicating to the controlling means either the value of the controlled variable the error, or the deviation.

701a The *primary element* is that portion of the measuring means which first either utilizes or transforms energy from the controlled medium to produce an effect in response to change in the value of the controlled variable. The effect produced by the primary element may be a change of pressure, force, position, electrical potential, or resistance.

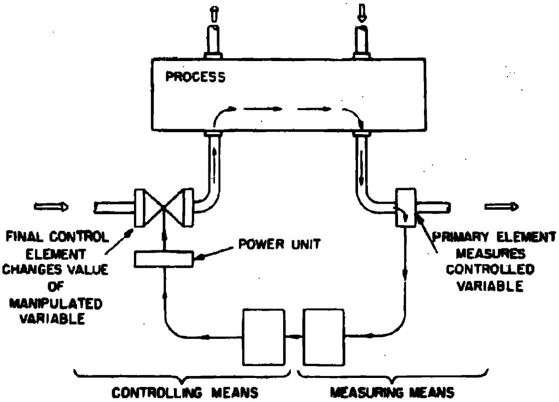
702 The *controlling means* consists of those elements of an automatic controller which are involved in producing a corrective action.

702a A *power unit* is a portion of the controlling means which applies power for operating the final control element.

702b The *final control element* is that portion of the controlling means which directly changes the value of the manipulated variable.

Referring to Fig. 10-20, it may be assumed that the measuring means is a thermometer system, and the controlling means consists of a pneumatic-type controller mechanism and a diaphragm-operated control valve.

A change in value of the controlled variable, the temperature of fluid leaving the process, first is ascertained by the primary element (the thermometer bulb) of the measuring means. This change is communicated by the measuring means to the controlling means. The controlling means produces a corrective action affecting the value of the manipulated variable, which is the flow of fluid entering the process. The corrective action operates through the final control element (the control valve) which directly changes the value of the manipulated variable. The power unit (the diaphragm motor) supplies power to the final control element.



PROCESS
FINAL CONTROL ELEMENT CHANGES VALUE OF MANIPULATED VARIABLE
POWER UNIT
PRIMARY ELEMENT MEASURES CONTROLLED VARIABLE
CONTROLLING MEANS
MEASURING MEANS

Fig. 10-20. Schematic diagram showing relationship of automatic controller elements.

Other examples of primary elements are the thermocouple for measuring temperature; the diaphragm and bellows for measuring pressure; and the orifice, rotameter, venturi, and flow nozzle for measuring rate of flow. All these elements first utilize or transform energy from the controlled medium while performing the duties of measurement.

An interesting example of a final control element is the control switch of a pyrometer for electric furnaces, where all current to the furnace is carried by the control switch without the use of auxiliary relays. In this case, the switch is the final control element. If an auxiliary relay were used, this relay would become the final control element.

Characteristics of Automatic Controllers. Just as the process proper has certain characteristics which affect control, so does the automatic controller. These characteristics are defined (ASME) and described briefly below.

102 A *self-operated controller* is one in which all the energy necessary to operate the final control element is derived from the controlled medium through the primary element.

701b A ***self-operated measuring means*** is one in which all the energy necessary to actuate the controlling means of an automatic controller is derived from the controlled medium through the primary element.

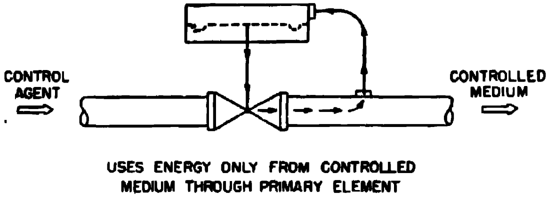
702c A *self-operated controlling means* is one in which all the energy necessary to operate the final control element is derived from the measuring means.

103 A *relay-operated controller* is one in which the energy transmitted through the primary element is either supplemented or amplified for operating the final control element by employing energy from another source.

701c A *relay-operated measuring means* is one in which the energy transmitted through the primary element is either supplemented or amplified for actuating the controlling means of an automatic controller by employing additional energy.

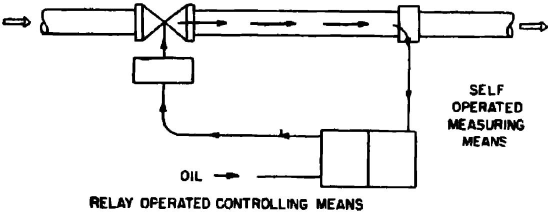
702d A *relay-operated controlling means* is one in which the energy transmitted from the measuring means is either supplemented or amplified for operating the final control element by employing additional energy.

A self-operated controller is illustrated in Fig. 10-21 which shows a diaphragm-type pressure-reducing valve operated by energy obtained only from the controlled medium through the primary element. A self-operated controller must have both self-operated measuring means and self-operated controlling means. It must derive all its energy through the primary element and may not derive energy separately from the controlled medium to obtain a relay-operated control.



CONTROL AGENT
CONTROLLED MEDIUM
USES ENERGY ONLY FROM CONTROLLED MEDIUM THROUGH PRIMARY ELEMENT

Fig. 10-21. Schematic diagram of self-operated controller.



SELF OPERATED MEASURING MEANS
OIL
RELAY OPERATED CONTROLLING MEANS

Fig. 10-22. Schematic diagram of relay-operated controller, with self-operated measuring means and relay-operated controlling means.

The self-operated measuring means of the pressure-reducing valve shown in Fig. 10-21 is the diaphragm, which also is the primary element. The diaphragm measures the pressure of the controlled variable and transforms this pressure to a force.

The self-operated controlling means of Fig. 10-21 consists of the diaphragm of the measuring means and the valve body and plug. The diaphragm force directly operates the valve plug, and the relative positions of the valve body and plug affect the value of the controlled variable. Note that in this example the controlled medium and the control agent are the same.

The relay-operated controller is illustrated in Figs. 10-22 and 10-23. A relay-operated controller must have at least one source of energy other than that derived from the controlled medium through the primary element to operate the final control element. A relay-operated controller either may have a self-opperated measuring means and a relay-operated controlling means; a relay-operated measuring means and a self-operated controlling means; or a relay-operated measuring means and a relay-operated controlling means. Figure 10-22 shows a self-operated measuring means and a relay-operated controlling means. Figure 10-23 shows a relay-operated measuring means and a relay-operated controlling means.

The self-operated measuring means of Fig. 10-22 may be a millivoltmeter pyrometer or a pressure-actuated thermometer, in which case the energy derived from the controlled medium through the primary element is transformed before actuating the controlling means. However, this energy is neither supplemented nor amplified by energy from another source.

If in Fig. 10-22 the nomenclature should be reversed, *i.e.*, a relay-operated measuring means and a self-operated controlling means, the resultant combination also would be a relay-operated controller. An example of such a combination would be a potentiometer pyrometer with balancing motor operating a final control element by means of a direct mechanical connection. In this case, the final control element may be an electrical rheostat or a small needle valve. The relay-operated measuring means, in this example the potentiometer, employs additional energy for actuating the controlling means other than the energy transmitted through the primary element.

Automatic-control Characteristics. Closely associated with the characteristics of automatic controllers are the characteristics of automatic control itself. Some of these characteristics are defined (ASME) and described below.

405 *Cycling* is a periodic change of the controlled variable from one value to another. ("Oscillation" is a synonymous term.)

104 The *desired value* is the value of the controlled variable which it is desired to maintain.

105 The *set point* is the position to which the control-point setting mechanism is set.

106 The *control point* is the value of the controlled variable which, at any instant, the automatic controller operates to maintain.

401 *Error* is the difference between the instantaneous value and the desired value of the controlled variable.

402 *Deviation* is the difference between the instantaneous value of the controlled variable and the value of the controlled variable corresponding with the set point.

403 *Offset* is a sustained deviation due to an inherent characteristic of positioning-controller action and is the difference existing at any time between the control point and the value of the controlled variable corresponding with the set point.

Cycling of the controlled variable is illustrated in Fig. 10-24. It is a continuous change of the controlled variable alternately increasing and decreasing in value. The time interval between two successive peaks of the cycle remains substantially constant nd is termed the "period" of the cycle. The amplitude of cycling is the maximum departure of the controlled variable from the average value of the cycle.

Three types of cycling of the controlled variable are shown in Fig. 10-24. Cycling in which the amplitude gradually decreases may be obtained, for example, with proportional-speed floating controller action. Cycling in which the amplitude is constant may be obtained with two-position controller action. Cycling in which the amplitude gradually increases is not suitable for automatic control.

The desired value of the controlled variable is determined by the operating requirements of the process. Usually, the set point of the automatic controller is adjusted so that the control point and the desired value will coincide.

The set point of an automatic controller is the position of the control-point-setting mechanism translated into units of the controlled variable. Generally, a set-point scale is provided. The set point may be varied manually or by automatic means, such as in time-schedule or ratio control. The control point is the value of the controlled variable maintained by the controller.

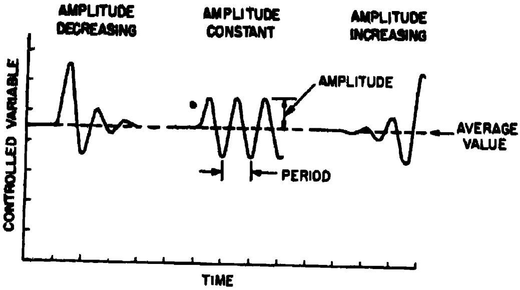

FIG. 10-24. Schematic diagram showing cycling of the controlled variable.

In some types of automatic controllers, *e.g.*, those with two-position differential gap or floating with neutral controller action, the control point becomes a control range of the controlled variable, and the set point is generally selected as the center of this range of values.

Figure 10-25 illustrates the condition at which the desired value, set point, and control point coincide. This type of controlled-variable record may be obtained by a proportional-plus-reset controller action correcting for a sustained change of process load. The set point was initially adjusted to coincide with the desired value; and the set point and control point coincide because of the floating-type controller action employed. In floating with neutral-zone controller action, the control point and the set point always coincide. The error and deviation coincide because of their respective associations with the desired value and set point.

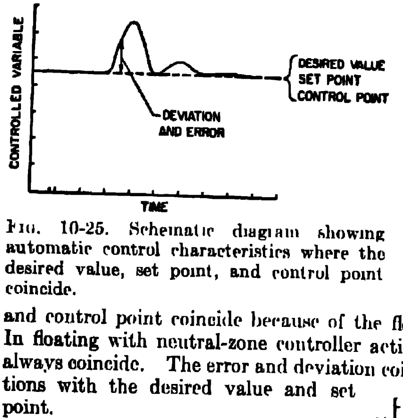

FIG. 10-25. Schematic diagram showing automatic control characteristics where the desired value, set point, and control point coincide.

Figure 10-26 illustrates the condition at which the desired value and set point coincide, and the control point differs from the set point by the amount of offset. This type of controlled-variable record may be obtained by a proportional-position controller action correcting for a sustained change of process load. The deviation and error coincide because the set point was initially adjusted to coincide with the desired value. In positioning-type controller action, the control point may lie anywhere within a predetermined range of values of the controlled variable. The control point may then differ from the set point by the amount of offset.

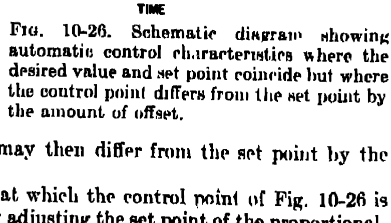

FIG. 10-26. Schematic diagram showing automatic control characteristics where the desired value and set point coincide but where the control point differs from the set point by the amount of offset.

Figure 10-27 illustrates the condition at which the control point of Fig. 10-26 is made to coincide with the desired value by adjusting the set point of the proportional-position controller of Fig. 10-26. The error which is associated with the desired value now differs from the deviation which is associated with the set point.

Modes of Automatic Control. In the following definitions, it is assumed that the automatic controller operates ideally, *i.e.*, it detects infinitesimal variations of the controlled variable and responds instantaneously in accordance with its predetermined action or mode. All numbered definitions are ASME.

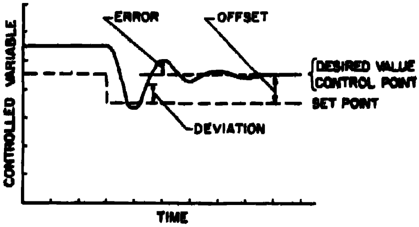

Fig. 10-27. Schematic diagram showing automatic control characteristics where the control point shown in Fig. 10-26 is made to coincide with the desired value by adjusting the set point of the proportional-position controller of Fig. 10-26.

501*ab* *Two-position single-point action* is that in which a final control element is moved from one of two fixed positions to the other at a single value of controlled variable.

501*aa* *Two-position differential-gap action* is that in which a final control element is moved from one of two fixed positions to the other when the controlled variable reaches a predetermined value from one direction, and subsequently is moved to the other position only after the variable has passed in the opposite direction through a range of values to a second predetermined value.

602 *Differential gap*, applying to two-position controller action, is the smallest range of values through which the controlled variable must pass in order to move the final control element in succession to both of its fixed positions.

501*b* *Multiposition action* is that in which a final control element is moved to one of three or more predetermined positions, each corresponding to a definite range of values of the controlled variable.

502*aa* *Single-speed floating action* is that in which a final control element is moved at a single rate.

601 *Neutral zone* is a predetermined range of values of the controlled variable in which no corrective action occurs.

601 *Floating speed*, applying to single or multispeed floating controller action, is the rate of motion of the final control element.

502*ab* *Multispeed floating action* is that in which a final control element is moved at two or more rates, each corresponding to a definite range of values of the controlled variable.

Two-position, single-point action is illustrated in Fig. 10-28. The two-position action, commonly termed, "on-off," is obtained at a point value of the controlled variable. The position of this point is adjusted within the range of the controlled variable by the set-point adjustment. The ON or OFF position of the final control element is determined by the direction of change of the controlled variable from the set point.

This type of controller action may be considered the equivalent of proportional-position action with zero proportional band; floating action with zero neutral zone and infinite floating speed; or two-position action with zero differential gap.

Two-position differential-gap action is shown in Fig. 10-29. The position of the final control element as the controlled variable passes the set point is determined by the direction of motion of the controlled variable as it passes through the differential gap. In this case, the control point becomes the differential gap, a fixed range of values of the controlled variable. The controlled variable must pass through the differential gap before a change of controller position takes place. When the controlled variable is within the differential gap, the controller maintains its previous position. The differential gap is commonly expressed in per cent of controller-scale range, and its position within the range is determined by the set-point adjustment.

Multiposition controller action is illustrated in Fig. 10-30. The three positions of the final control element correspond to three predetermined ranges of the controlled variable.

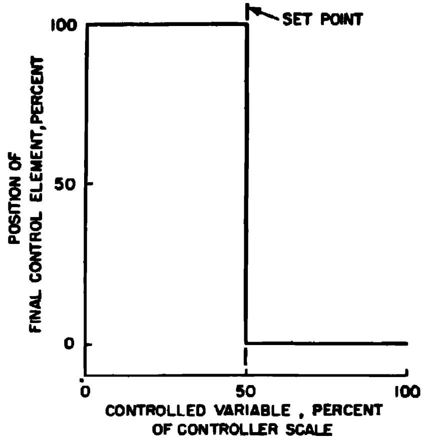

FIG. 10-28. Schematic diagram showing two-position single-point controller action

Single-speed floating action is illustrated in Fig. 10-31. The floating speed is the rate of motion of the final control element, which is a predetermined single value. It is generally expressed as the per cent of full-range motion of the final control element per minute. A neutral zone, in which no motion of the final control element occurs, is employed. The control point becomes the neutral zone. The direction of motion of the final control element is determined by the direction of change of the controlled variable from the neutral zone. The neutral zone is commonly expressed in per cent of controller-scale range, and its position within th range is determined by the set-point adjustment.

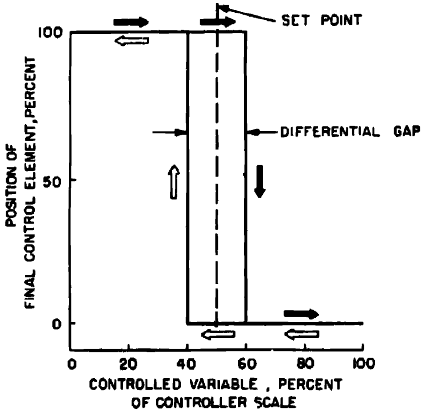

FIG. 10-29. Schematic diagram showing two-position differential-gap controller action.

Multispeed floating controller action is illustrated in Fig. 10-32. It differs from single-speed floating action in that there is more than one rate of motion of the final

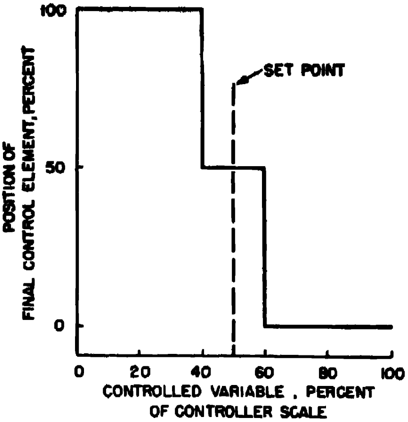

Fig. 10-30. Schematic diagram showing multiposition controller action.

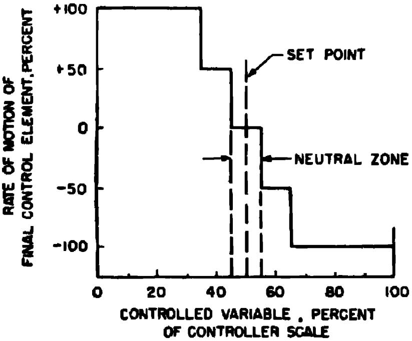

Fig. 10-31. Schematic diagram showing single-speed floating controller action.

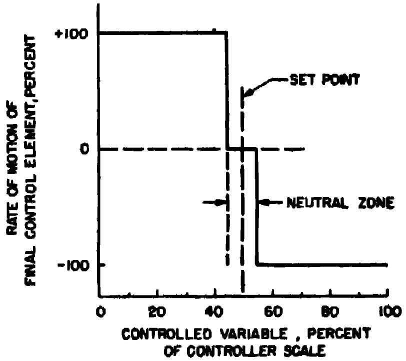

Fig. 10-32. Schematic diagram showing multispeed floating controller action.

control element. Each rate of motion corresponds to a predetermined range of the controlled variable.

501c *Proportional-position action* is that in which there is a continuous linear relation between value of the controlled variable and position of a final control element.

603 *Proportional band*, applying to proportional-position controlled action, is the range of values of the controlled variable which corresponds to the full operating range of the final control element.

501d *Average-position action* is that in which there is a predetermined relation between value of the controlled variable and the time-average position of a final control element which is moved periodically from one of two fixed positions to the other.

502ad *Floating average-position action* is that in which there is a predetermined relation between value of the controlled variable and rate of change of the time-average position of a final control element which is moved periodically from one of two fixed positions to the other.

Proportional-position controller action is illustrated in Fig. 10-33. The proportional band is adjustable and is shown equal to 40 per cent of the controlled-variable controller-scale range.

The proportional band is commonly expressed in per cent of controller-scale range or, particularly in the absence of a controller scale, in units of the controlled variable. The set point is also adjustable and is shown at 40 per cent of the controller-scale range. The intersection of the set point and the proportional-position action line determines the position of the final control element when the controlled variable is at the set point. In this illustration (Fig. 10-33), the position of the final control element is at 50 per cent. As the controlled variable deviates from the set point, the final control element takes a position directly proportional to the deviation, as indicated by the proportional-position action line.

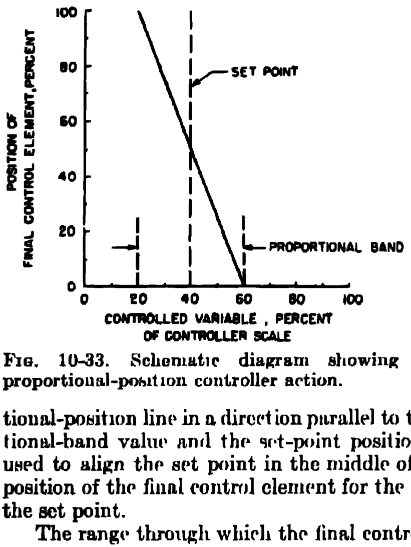

FIG. 10-33. Schematic diagram showing proportional-position controller action.

Proportional-position controllers are frequently equipped with a manual adjustment for shifting the proportional-position line in a direction parallel to the controlled-variable axis. The proportional-band value and the set-point position are not changed. This adjustment is used to align the set point in the middle of the proportional band and to adjust the position of the final control element for the purpose of aligning the control point with the set point.

The range through which the final control element may operate may be less than 100 per cent. It is dependent upon the relative values of the proportional band and the position of the band on the controller scale. As the value of the proportional band is increased above 100 per cent controller scale, the range of the final control-element position is decreased below 100 per cent for any position of the set point.

Average-position controller action is equivalent to a combination of positioning controller action and a two-position final control-element action operating in a periodic manner. The cyclic period of the two-position final control-element action is predetermined and fixed. The change from one position, "time on," to the other position, "time off," is nearly instantaneous.

The average-position action, illustrated in Fig. 10-34, is of the proportional type. The percentage "time on" or "time off" is proportional to the deviation of the controlled variable from the set point.

Floating average-position controller action is equivalent to a combination of floating controller action and a two-position final control-element action operating in a periodic manner.

FIG. 10-35. Schematic diagram showing floating average-position controller action of the single-speed type.

The floating average-position controller action, illustrated in Fig. 10-35, is of the single-speed type. The rate of change of the percentage "time on" or "time off" is a fixed value when the controlled variable within the neutral zone, the percentage "time on" or "time off," is constant.

502ac *Proportional-speed floating action* is that in which there is a continuous linear relation between value of the controlled variable and rate of motion of a final control element.

605 *Floating rate*, applying to proportional-speed floating controller action, is the rate of motion of the final control element corresponding to a specified deviation.

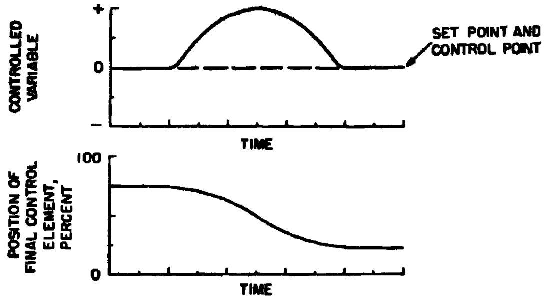

FIG. 10-36. Schematic diagram showing the response of a proportional-speed floating-action controller.

The response of a proportional-speed floating-action controller is illustrated in Fig. 10-36. The deviation of the controlled variable is caused by a sustained change in process load. The controlled variable always returns to the set point at the completion of the corrective action of the controller; this is a characteristic of all floating-type controller actions. The final control element takes a new position to correct for the process-load change. The manner in which the corrective action is accomplished is a function of the controlled-variable deviation, as well as the floating-rate adjustment of the controller action.

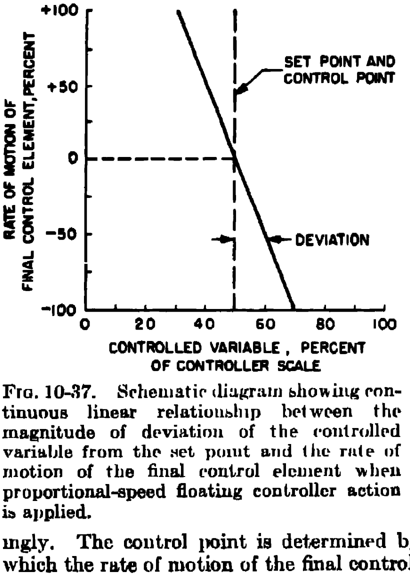

FIG. 10-37. Schematic diagram showing continuous linear relationship between the magnitude of deviation of the controlled variable from the set point and the rate of motion of the final control element when proportional-speed floating controller action is applied.

Figure 10-37 shows the continuous linear relationship between the magnitude of deviation of the controlled variable from the set point and the rate of motion of the final control element, when proportional-speed floating controller action is applied. The slope of the curve of Fig. 10-37 is determined by the value of the floating rate of the controller action. If the set point is shifted along the axis of the controlled variable, the controlled point moves correspondingly. The control point is determined by the value of the controlled variable at which the rate of motion of the final control element is zero.

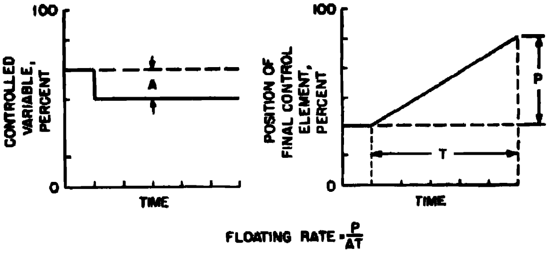

FIG. 10-38. Schematic diagram showing the floating rate of proportional-speed floating controller action.

The floating rate of proportional-speed floating controller action is illustrated in Fig. 10-38. It is the rate of change of position of the final control element divided by the controlled-variable deviation initiating the corrective action. Floating rate is commonly expressed in per cent of full range motion of the final control element per minute per per cent deviation.

504aa *Proportional-plus-reset action* is that in which proportional-position action and proportional-speed floating action are combined.

606 *Reset rate*, applying to proportional-plus-reset controller action and proportional-plus-reset-plus-rate controller action, is the number of times per minute that the effect of the proportional-position action upon the final control element is repeated by the proportional-speed floating action.

503a *Rate action* is that in which there is a continuous linear relation between rate of change of the controlled variable and position of a final control element.

504b *Proportional-plus-derivative action* is that in which proportional-position action and derivative action are combined.

607 *Rate time*, applying to proportional-plus-rate controller action and proportional-plus-reset-plus-rate controller action, is the time interval by which the rate action advances the effect of the proportional-position action upon the final control element.

504ca *Proportional-plus-reset-plus-rate action* is that in which proportional-position action, proportional-speed floating action, and rate action are combined.

The response of a proportional-plus-reset action controller is illustrated in Fig. 10-39. The deviation of the controlled variable is caused by a sustained change in process load. The controlled variable returns to the set point at the completion of the corrective action of the controller owing to the floating-type controller-action component employed. The final control element takes a new position corresponding to the new value of the process load. The manner in which the corrective action is accomplished is a function of the controlled-variable deviation, as well as the adjustments of the proportional band and the reset rate. The proportional-band adjustment simultaneously affects the proportional-speed floating action in such a manner that the reset remains constant at its set value.

FIG. 10-39. Schematic diagram showing the response of a proportional-plus-reset action controller.

When proportional-speed floating action is combined with proportional-position action, the proportional-speed floating action is termed "reset action."

Reset rate of a proportional-plus-reset controller is illustrated in Fig. 10-40. In this illustration, proportional-position action is obtained by an instantaneous change in set-point position with the other variables remaining constant. Reset rate is the rate of change of position of the final control element resulting from the proportional-speed floating-action component, divided by the change in position of the final control element resulting from the proportional-position action component, with the same deviation in both cases. The two controller actions are initiated at the same instant.

Reset rate is commonly expressed as the number of "repeats" per minute originating from a given deviation of the controlled variable. Reset rate is determined by dividing (1) the travel of the final control element in 1 min due to the effect of the proportional-speed floating action by (2) the travel of the final control element due to the effect of the proportional-position action.

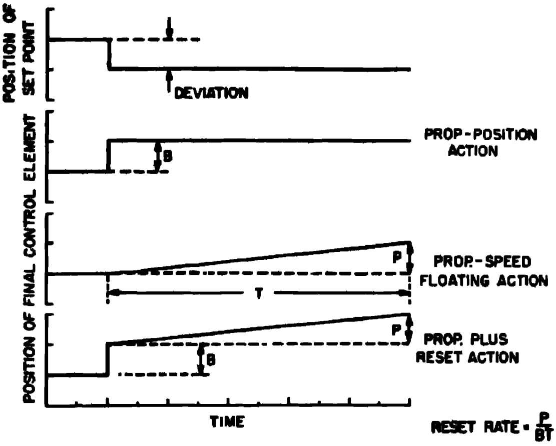

Fig. 10-40. Schematic diagram showing the reset rate of a proportional-plus-reset controller.

The reset rate is fixed by a manually set adjustment; it is independent of controlled-variable deviation and the proportional-band adjustment of the controller.

Fig. 10-41. Schematic diagram showing the response of a proportional-plus-rate action controller.

Proportional plus rate action is that in which proportional-position action and rate action are combined. The rate-action component employs a derivative of rate of change of the controlled variable and the position of the final control element.

The response of a proportional-plus-rate action controller is illustrated in Fig. 10-41. The deviation of the controlled variable is caused by a temporary process-load change of negligible duration. The controlled variable returns to the set point, and the final control element returns to its original position. If the process-load change were sustained, the controlled variable would line out at a new control point which would differ from the set point by the amount of offset. The manner in which the corrective action is accomplished is a function of the controlled-variable deviation, as well as the adjustments of the proportional band and rate time.

TIME
RATE TIME = T

Fig. 10-42. Schematic diagram showing the rate time of a proportional-plus-rate action controller.

Rate time of a proportional-plus-rate action controller is illustrated in Fig. 10-42. It is the advance in position of the final control element resulting from the rate-action component. The advance is measured in units of time, generally minutes, and is equal to the time required for a selected motion of the final control element due to the effect of proportional-position action alone, minus the time required for the same motion due to the effect of proportional-position-plus-rate actions, with the same rate of change of the controlled variable in both cases. The rate action and proportional-position action are initiated at the same instant by the deviation of the controlled variable.

The response of a proportional-plus-reset-plus-rate action controller is illustrated in Fig. 10-43. The deviation of the controlled variable is caused by a sustained change of process load. The controlled variable returns to the set point at the completion of the corrective action of the controller because of the floating-type controller-action component employed. The final control element takes a new position corresponding to the new process-load value. The manner in which the corrective action is accomplished is a function of the controlled-variable deviation, as well as the adjustments of the proportional band, the reset rate, and the rate time.

PROP PLUS RESET PLUS RATE ACTION
TIME

Fig. 10-43. Schematic diagram showing the response of a proportional-plus-reset-plus-rate action controller.

Proportional-plus-reset-plus-rate controller action is that in which there is a predetermined relation between the position of the final control element and (1) the deviation of the controlled variable, (2) the time integral of the deviation, and (3) the rate of change of the deviation.

The proportional-position reset and rate-controller action components occur simultaneously and are initiated by the controlled-variable deviation. The proportional-band value of the proportional-position-action component directly affects the magnitude of the floating and rate-controller actions. In automatic controllers having proportional-plus-reset-plus-rate action, a reset-rate adjustment and a rate-time adjustment, the proportional band may be adjusted without affecting the set value of the reset rate or the rate time.

The following groups of terms are of a general nature and define basic controller actions:

404 *Corrective action* is predetermined variation of the manipulated variable initiated by a deviation.

501 *Positioning action* is that in which there is a predetermined relation between value of the controlled variable and position of a final control element.

501*a* *Two-position action* is that in which a final control element is moved from one of two fixed positions to the other. ("Open and shut action" or "on-off" action are synonymous terms.)

502 *Integral action* is that in which there is a predetermined relation between an integral function of the controlled variable and position of a final control element.

502*a* *Floating action* is that in which there is a predetermined relation between value of the controlled variable and rate of motion of the final control element.

503 *Derivative action* is that in which there is a predetermined relation between a derivative function of the controlled variable and position of a final control element.

504 *Multiple action* is that in which two or more controller actions are combined.

504*a* *Proportional-plus-floating action* is that in which proportional-position action and floating action are combined.

504*c* *Proportional-plus-floating-plus-derivative action* is that in which proportional-position action, proportional-speed floating action, and derivative action are combined.

AUTOMATIC-CONTROL-SYSTEM APPLICATIONS

Previous parts of this section on instrumentation point out the many variations which enter into process control. Instrumentation engineering involves an evaluation of all these variations, including process characteristics and automatic-controller characteristics. Once these variations are evaluated, the engineer must select the instruments with characteristics which most appropriately meet the requirements of the process, not forgetting the cost of the installation. Some idea of the numerous ways in which instruments and controls can be applied to a process can be obtained from the examples which follow:

Figure 10-44 illustrates a simple *open-kettle temperature-control system*. The measuring means comprises a pressure-type thermometer bulb located through the side of the vessel. Internal pressure in the thermal system is transmitted to a measuring spiral within the instrument case by means of armored capillary tubing. Automatic control is accomplished pneumatically by positioning a diaphragm motor valve on the steam-supply line to the heating coils.

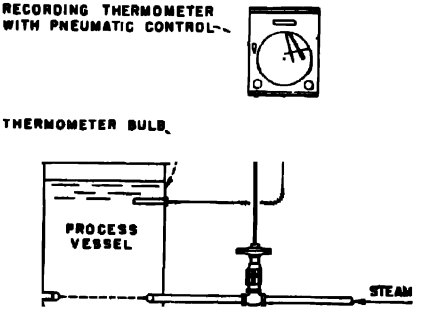

FIG. 10-44. Simple open-kettle temperature-control system.

In order to increase production, it may be desirable to heat the contents of the kettle as quickly as possible to a given temperature and then hold the kettle at that temperature. The heating time is a controllable factor which should be reduced to a minimum because it is unproductive time. This means that, during the heating time, a large heat input is required, and when the control temperature is reached, a much smaller heat input, sometimes only sufficient to supply radiation losses, is required. To meet the demands of such operations, two controlled valves, as illustrated in Fig. 10-45, may be used in parallel—a large valve and a smaller valve. If the controlled output air pressure from the instrument varies from 0 to 15 psi with 7.5 psi at the control point, the large valve will be designed to throttle from an open to a closed position when the diaphragm air pressure is varied from 0 to 7.5 psi, and the smaller valve will be designed to proportion over the entire range from 0 to 15 psi. Thus, both valves will be open in the early stages of heating. The large valve will move toward a closed position and will be closed when the set point is reached, and the smaller valve will be throttling in mid-position at the set point.

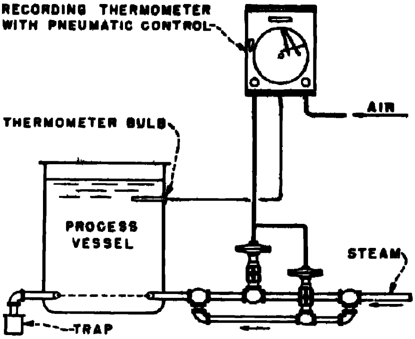

Fig. 10-45. Temperature-control system designed for rapid heating.

In some operations, it is desirable to employ a *jacketed kettle* and circulate the heating or cooling medium through the jacket. Figure 10-46 is a schematic diagram of a temperature controller applied to such an installation. In this case, a three-way valve is used to direct any part or all the flow of the heating medium through the jacket. That which does not go through the jacket is by-passed around it. Three-way valves in such applications permit a large quantity to pass through the jacket for quick heating and a small quantity for holding the temperature at the set point, similar to the two-valve application of Fig 10-15, and they do not materially restrict the total flow of heating medium being controlled.

Fig. 10-46. System showing use of three-way diverting valve in temperature control.

Often it is desirable to bring an open kettle up to a given temperature, hold it at that temperature for a given length of time, and then shut off the heating medium and discharge the contents of the vessel. A process-control system to perform these operations is shown in Fig. 10-47. A pressure switch in the air line to the steam valve closes when the temperature reaches the set point. The pressure switch starts a timer, and at the end of the period for which the timer is set, the three-way solenoid valves in the air lines to the steam valve and to the discharge valve are operated. Both the steam valve and the discharge valve are normally closed so that they will move to a closed position upon air failure. Therefore, at the end of the timing period,

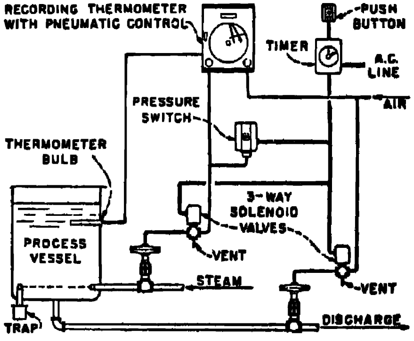

Fig. 10-47. Electric-pneumatic time temperature control system.

the three-way solenoid valve in the air line to the steam valve closes and bleeds the air from the diaphragm, and the steam valve closes; also the three-way valve in the air line to the discharge valve closes its exhaust port and admits air to the diaphragm from the supply line to open the discharge valve. The steam valve remains closed, and the discharge valve remains open. When the vessel is recharged, the operator pushes the start button which momentarily opens the electric-current supply. This automatically resets the timer to its starting position and opens the steam valve and closes the discharge valve. In the meantime, while the vessel was being emptied, the temperature dropped below the set point, and the pressure switch opened. The vessel now can be recharged to repeat the heating and holding cycle. In plants where a number of vessels are under the supervision of one operator, it may be desirable to incorporate signal lights with the automatic equipment to indicate when the vessels are being emptied.

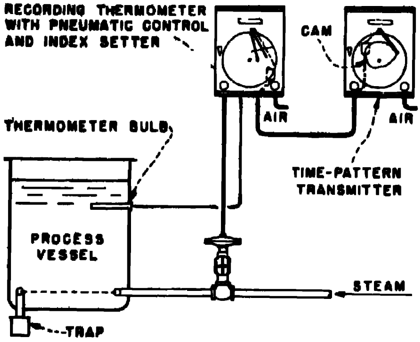

Fig. 10-48. Pneumatic time temperature control system.

In some operations, it is desirable that the *temperature follow a predetermined program*. Figure 10-48 is a schematic diagram of such an installation in which the control index of the recorder is moved by varying air pressure from the transmitter. The output air pressure from the transmitter varies in direct proportion to the radius of the cam mounted on it. Thus, the control instrument automatically controls to the time-temperature pattern of the cam. The cams are usually constructed of aluminum sheets. Graduations are printed on the aluminum disk similar to the graduations printed on a paper chart. This makes it possible to keep transmitter disks on hand and to cut new cams from them as required. The index of the control instrument can be set manually for operations when an automatic time-temperature program is not required.

Where there is energy dissipation within a vessel, as with *exothermic reactions*, it often is necessary to remove heat from the process to prevent the temperature from becoming excessive. Chromium plating is an example of a process in which energy is dissipated in the bath owing to the passage of electric current. Figure 10-49 illustrates the application of temperature control to a plating tank. The bath contains both heating (steam) and cooling (water) coils. The valves in these lines are connected to the output air line from the control instrument. One valve opens with an increase in air pressure, and the other valve closes with an increase in air pressure. The valve springs are so adjusted that one valve is open at 0 psi and closed at 8 psi, while the other valve is open at 15 psi and closed at 9 psi. Thus, when the air pressure on the diaphragms is between 8 and 9 psi, both valves will be closed. The instrument-control mechanism is adjusted to a narrow proportioning band with an output air pressure of 8.5 psi at the set point. When the temperature rises above the set point, the steam valve is closed, and the water valve opens. When the temperature drops below the set point, the water valve is closed, and the steam valve opens.

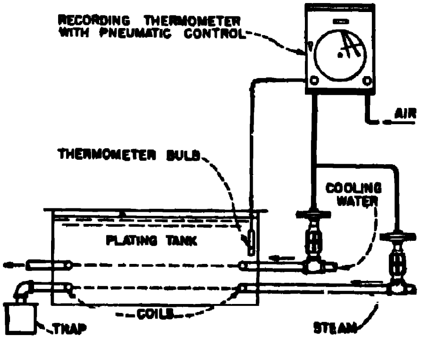

Fig. 10-49. Combined heating and cooling in one control system.

Another method of obtaining both *heating and cooling* in a control system is shown in Fig. 10-50. In this system, a tank of hot water is automatically held at the set point by a separate controller which regulates the flow of steam and water to the tank. The tank is provided with an overflow. A pump circulates hot water from the tank through a closed-coil heater in the process vessel or through a jacket surrounding the vessel. The process temperature controller operates a three-way valve to regulate the flow of hot water to the process or by-pass it back to the auxiliary tank. With a high rate of circulation, very close control can be obtained with this method, and it possesses the advantage of limiting the temperature of heating medium where high temperatures would cause decomposition. The steam- and water-valve arrangement on the heating tank is similar to Fig. 10-49.

FIG. 10-50. Combined heating and cooling control of process-control agent.

Figure 10-51 illustrates an open vessel in which the liquid contents are *heated by means of an electric immersion element*. The power supply to the heating element is turned on and off automatically by means of a mercury switch in the control instrument. Mercury switches such as this are designed to break at about thirty amperes at 115 volts. For greater power requirements, an auxiliary contactor is necessary.

A number of other systems have been devised to regulate the power input to electrically heated processes, including the following:

1. Automatic adjustment of resistances in series with the heating elements
2. Use of power input controllers which are a type of circuit interrupter in which the length of time that the power is supplied to the process is automatically varied in reference to departure from the set point
3. Automatically varying the voltage applied to the heating elements by means of multitap transformers or induction voltage regulators
4. Automatically varying the power supplied to the heating elements by means of a saturable reactor

Adjustable resistors, input controllers, multitap transformers, and induction regulators generally are operated by reversible motors from a single-pole double-throw mercury switch operated by the automatic-control instrument. When the temperature is at the set point, the position of the switch is such that the circuits to the reversing motor are open so that the power input to the process remains at that value.

The saturable-reactor type of electric control system receives impulse from the change in position of the sliding contact on a resistor.

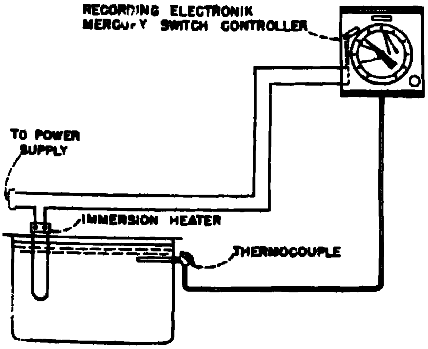

FIG. 10-51. On-off temperature-control system where electric immersion heater is used.

In Fig. 10-52, a thermocouple is located in the discharge of an electrically heated continuous-fluid heater. The output air pressure of the pneumatic control instrument is applied to a small air-operated slide-wire. The purpose of using the pneumatic control instrument to operate the slider is to take advantage of the adjustable proportional band and reset rate incorporated in its control system. These control characteristics are necessary for good control on continuous processes in which the throughput varies.

The potential unbalance caused by the change in position of the sliding contact is amplified electronically to regulate the amount of direct current in the saturating winding of a saturable-core reactor. The power supply is connected to the primary of the saturable reactor, and the heating element is connected to the secondary. As the direct current through the saturating winding varies, more or less power is transmitted from the primary to the secondary to which the heating element is connected.

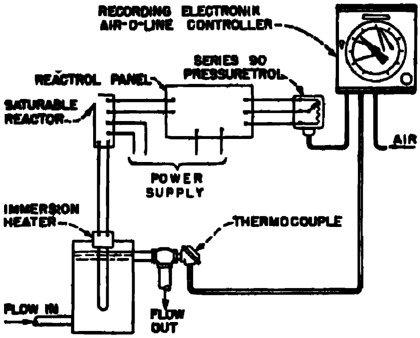

FIG. 10-52. Control system for saturable-reactor-type electric heater.

In most heating operations in *closed vessels*, such as autoclaves, the upper space in the vessel is filled with steam. In such cases, a pressure controller may be used for regulating the flow of the heating medium. The steam pressure is an indirect measure of the temperature. Thus, pressure controllers may be used in place of temperature controllers and have the advantages of lower cost, simplicity of operation and installation, and often better control because of less lag. However, when pressure control is used, it is necessary to vent entrapped air or other gases released during the heating-up period. Pressure control in lieu of temperature control may not be satisfactory for processes requiring the introduction of inert or other gases.

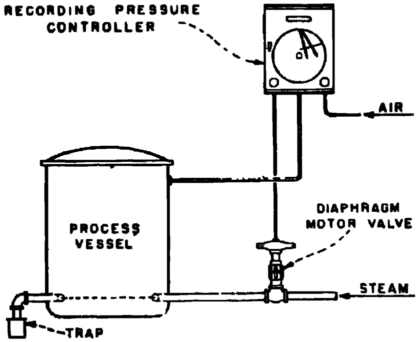

FIG. 10-53. Typical pressure-control system for a closed vessel.

Figure 10-53 shows a pressure controller applied to a closed vessel. If direct temperature control is required, owing to the presence of inert gases or other reasons, the system illustrated in Fig. 10-54 can be used. However, if either temperature or pressure is controlled, the uncontrolled temperature or pressure can be recorded on the same chart where desired.

Trap

FIG. 10-54. Temperature control of a closed vessel with pressure recorded.

Suppose that the upper space in a closed vessel is filled with steam and that a pressure recorder connected to it reads 100 psi. If a thermometer bulb partly filled with water is inserted in the same space and is connected to read on the same chart, it will also read 100 psi. This combination has been used to detect the presence of gases in closed vessels, such as paper digesters, by noting whether the pressure pen records the same value as the temperature pen. When other vapors are present, as in distillation columns, the thermometer bulb can be partly filled with the condensed vapors, and the difference between the temperature and pressure pens then will be a measure of the composition of the vapor in the column compared to the vapor in the thermometer bulb.

The pressure in closed vessels can be reduced *below atmospheric pressure* by means of a steam-jet ejector. As a rule, steam-jet ejectors will not operate satisfactorily over a wide range of steam flow. By setting the steam flow to the ejector at its optimum value, good control can be obtained by regulating a valve opening to atmosphere. Such an installation is illustrated in Fig. 10-55. In l-p operations, it is often necessary to use absolute-pressure controllers to obtain consistent results. Absolute-pressure controllers compensate for variations in atmospheric pressure. When centrifugal pumps are used to reduce the pressure, control may be obtained by regulating a valve located in the suction line of the pump, as in Fig. 10-56.

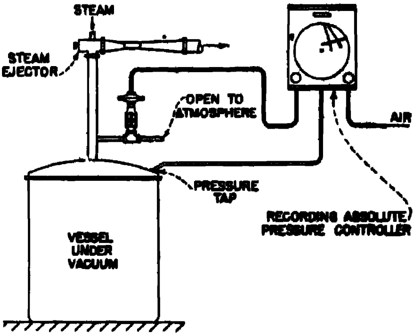

Fig. 10-55. Vacuum control of a steam-ejector system.

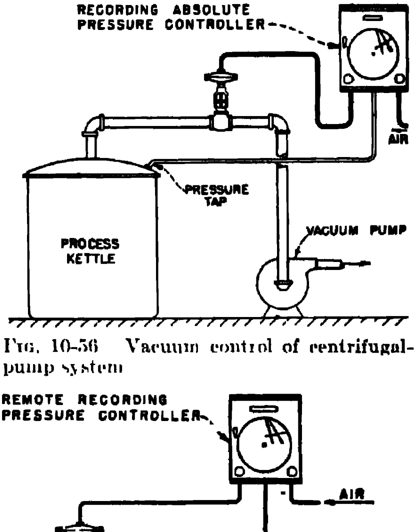

Fig. 10-56. Vacuum control of centrifugal-pump system.

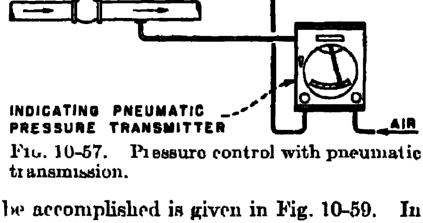
Pneumatic transmission of flow, temperature, pressure, and liquid-level measurements from process locations to a central control board was originally developed to avoid the use of electricity for this purpose in plant areas where explosive atmospheres are possible. A further advantage is the complete isolation from the control board of all process piping containing high pressures or hazardous fluids. A pressure-control system using pneumatic transmission is shown in Fig. 10-57. The indicating-pressure transmitter is located near the h-p line on the processing unit and transmits the pressure reading to the recording control instrument which operates the control valve in the pipe line. To reduce lag, a transmitter equipped with control often is used.

Automatic control of flow and liquid level represents the largest field of application for *differential-pressure controllers* in the process industries. Figure 10-58 is a schematic diagram of a typical flow-control installation in which the controlled valve is located in the flow line A differential mercury manometer connected across the orifice transmits the movement of its mercury electrically to a recording control instrument which, in turn, operates the valve in the flow line to maintain a constant differential pressure across the orifice and consequently a uniform rate of flow in the pipe.



REMOTE RECORDING PRESSURE CONTROLLER
AIR
HIGH PRESSURE LINE
INDICATING PNEUMATIC PRESSURE TRANSMITTER
AIR

Fig. 10-57. Pressure control with pneumatic transmission.

Often it may be desirable automatically to control one *rate of flow in direct proportion to another rate of flow*. A schematic diagram showing how this can be accomplished is given in Fig. 10-59. In the upper diagram, a meter body or manometer connected across the orifice in the primary flow line operates a pneumatic mechanism which develops an air pressure in direct proportion to the differential pressure across the orifice. This air pressure is transmitted to the control instrument connected across the orifice in the secondary flow line where, by means of a bellows-operated mechanism, it moves the control index. Thus, the set point of the controller regulating the secondary flow is moved in proportion to the primary flow. The mechanism in the secondary-flow controller is adjustable so that the ratio of the two flows can be varied. Maximum and minimum limits also can be set for the secondary-flow rate.

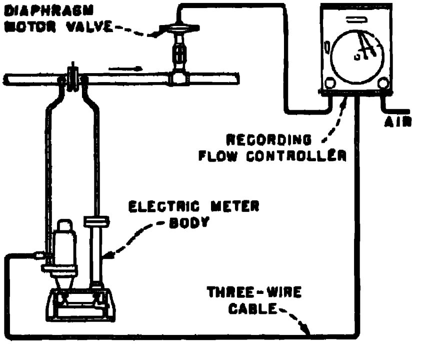


Fig. 10-58. Typical flow-control system with electrical transmission.

The lower diagram (Fig. 10-59) shows how pneumatic transmission can be used in a *ratio flow-control system* to permit locating the recording controller remotely with respect to the primary- and secondary-flow lines. It is possible by using equipment similar to that shown in Fig. 10-59 to reset the control index of a flow controller from variations in liquid level or to reset the control index of a pressure controller from variations in temperature or other combinations that may be desirable.

Fig. 10-59. Two common arrangements for ratio flow control.

Differential-pressure recorders also are used in connection with continuous filters, screens, and heat exchangers to reveal undesirable operating conditions such as the accumulation of scale or foreign material which affect the efficiency of the equipment.

Figure 10-60 illustrates the application of a differential-pressure control to maintain automatically the *level in a closed vessel under pressure*. Instruments of this type can be adjusted to hold the level within close limits, but this is not always desirable. For example, the level in an accumulator tank is not important until the tank is quite full or almost empty. For such applications, the controller can be adjusted to permit the level to change between wide limits, and where these limits are reached, the discharge valve will move to make large changes in the rate of discharge to prevent the tank from filling or becoming empty.

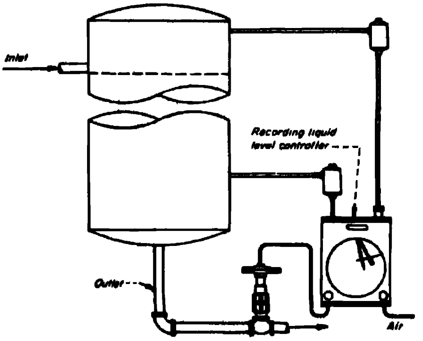

Fig. 10-60. Differential-pressure-type liquid-level control system.

There are occasions when it is desirable to *record or control the difference in temperature between two points* in a process or to control one temperature at a fixed difference with respect to another. This can be accomplished by using two thermocouples connected differentially to a potentiometer. The temperature difference across heat exchangers, compressors, centrifugal pumps, or between the heating jacket and column on adiabatic laboratory stills are but a few applications for this arrangement. A diagram of such an application is shown in Fig. 10-61.

Heat exchangers are used to heat or cool, with heat conservation as a possible dividend. The temperature of the fluid being heated or cooled can be controlled automatically by regulating the rate of flow of the fluid through the exchanger by means of a temperature controller responsive to the outlet temperature. If it is not feasible to put a control valve in this line, it may be placed in the line of the heating or cooling fluid, but the control may not be so close with the valve in this location because of the increased time required for the effect of a change in flow rate to be felt by the control instrument.

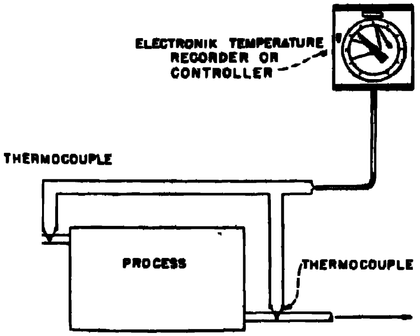

Fig. 10-61. Two thermocouples connected to measure the difference in temperature between two points.

Figure 10-62 shows a heat exchanger in which hot oil is being cooled to a constant lower temperature by water. For the purpose of water conservation and control stabilization, the outlet-water temperature is controlled by an inexpensive nonindicating controller which regulates the flow of water through the exchanger. The oil-temperature controller operates a three-way valve which divides the oil flow into two parts; one part goes through the heat exchanger, and the other part by-passes the heat exchanger. The part that goes through the exchanger is cooled below the desired final temperature. Upon leaving the exchanger, the cooled oil is mixed with the hot oil by-passed around the exchanger. Thus, the temperature controller blends hot oil and cold oil to obtain oil at the desired temperature. In this system, a change in valve position is felt very quickly by the temperature controller, and only a controller that will respond quickly should be used.

In some cases, a liquid is heated by steam in a heat exchanger. If the exchanger has excess capacity, a pressure controller can be used to regulate the flow of steam, and the final temperature of the liquid also can be recorded on the same chart.

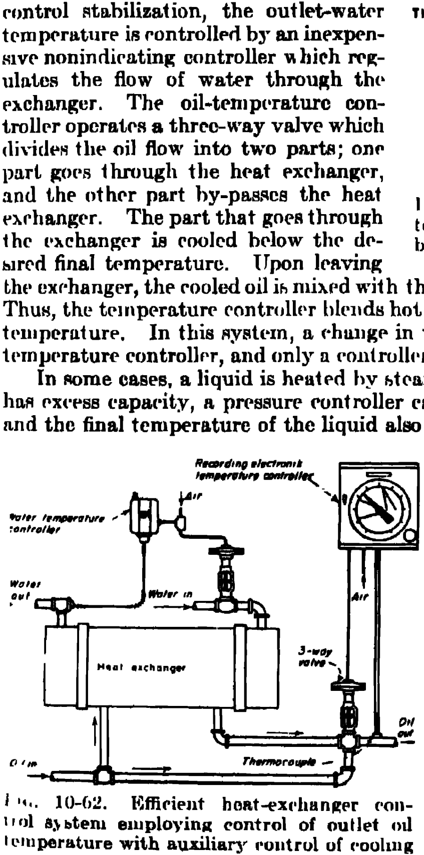

Fig. 10-62. Efficient heat-exchanger control system employing control of outlet oil temperature with auxiliary control of cooling water.

Dowtherm vapor is used as a high-temperature heating medium in many of the process industries. Figure 10-63 is a diagram of an automatic-control system applied to an oil-fired Dowtherm vaporizer. A pressure controller responsive to the outlet pressure of the vaporizer regulates the flow of oil and air to the burner. A photoelectric flame detector and pressure switches in the air and oil lines are safety devices to open the circuit of the solenoid valve to shut off the oil supply and sound an alarm when the air pressure is too low, when the oil pressure is too low, or if the flame goes out. On electrically heated Dowtherm vaporizers, the pressure controller can be used to operate a switch to open and close the circuit to the heating elements or to operate the slider on a potential divider, as shown previously for the control of electric heating elements by means of saturable reactors.

Kilns used for drying may be automatically controlled in response to the temperature of the exit material. The material dried in kilns is usually in the form of small particles so that a stationary thermocouple can be placed in the stream of material leaving the kiln. Care should be taken so that the thermocouple will respond to changes in temperature of the material and not be affected by air currents.

Figure 10-64 is a *kiln-control system* in which the oil burner is regulated from an instrument connected to a radiation pyrometer sighted on the material in the kiln or leaving the kiln.

FIG. 10-63. Typical control system for oil-fired Dowtherm vaporizer.

Dust is a problem around most kilns, and the air-cooled fitting not only cools the radiation heat, but it prevents dust from depositing on the lens. The location of the radiation pyrometer should be selected so that the line of sight does not include any part of the flame.

When the *rate of drying* is to be controlled, wet- and dry-bulb measurements of the air prior to its contact with the material are desirable. If the wet and dry bulbs are located in the air stream leaving the materials, a measure of the moisture from the material is obtained. The rate of drying may be accelerated by introduction of fresh air and retarded by introduction of water vapor. It should be borne in mind that, when applying control equipment to driers, moisture removed is carried away in the exit air, and the distribution of air in the drier is important from the standpoint of uniform drying. The air velocity across the wet bulb should be at least 10 ft per sec to ensure sufficient evaporation.

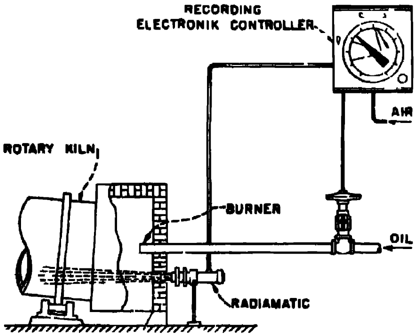

FIG. 10-64. Temperature-control system for oil-fired rotary kiln.

Direct measurement of relative humidity by means of hair elements is restricted to temperatures below 40°C, and they should be used only in clean atmospheres because grease and dust close the pores of the hair, and it will not respond rapidly to moisture changes.

Thermocouples, particularly pencil-type couples, can be used satisfactorily for wet-bulb measurements. The wet bulb should be sufficiently long to preclude erroneous readings due to heat conduction to the hot junction of the thermocouple. When relative humidities above 90 per cent are involved, careful consideration should be given to the sensitivity and accuracy of the instruments because the wet- and dry-bulb temperatures approach the same value at 100 per cent.

Figure 10-65 shows a wet- and dry-bulb-control installation on a *recirculating drier.* The sensitive elements are located in the air leaving the drier. The dry bulb controls dampers either to direct air through the heater or to by-pass it around the heater. The wet bulb controls admission of fresh and release of moisture-laden air by means of a three-way damper.

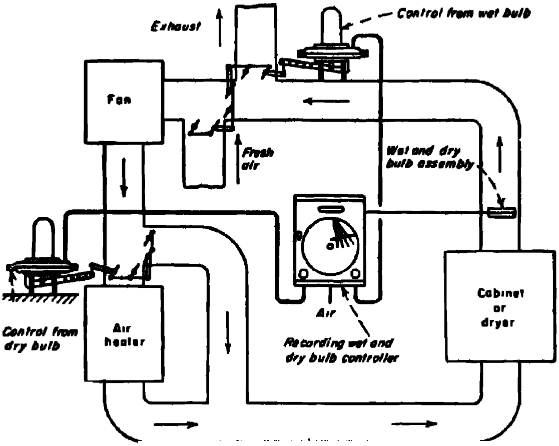

Fig. 10-65. Humidity-control system for recirculating drier.

At times it is desirable to have a valve close and stay closed after a process has reached a predetermined condition (*automatic-shutdown systems*). In Fig. 10-66, a pneumatic controller is shown with its control index set at a predetermined value. When the value is reached, the output air pressure of the controller drops below 15 psi, and the pressure switch opens the circuit to a three-way valve which shuts off the air to the valve and permits the air on the diaphragm to discharge to atmosphere. The diaphragm valve closes and stays closed until the three-way valve is opened again by means of the manual-reset push button.

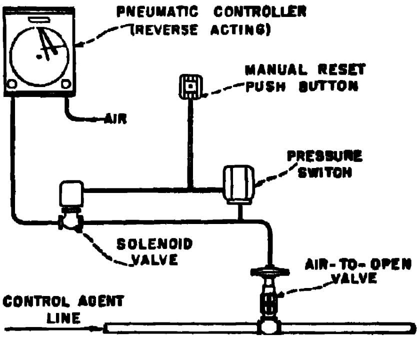

Fig. 10-66. Automatic safety shutdown system with combination electric and pneumatic controls.

Figure 10-67 shows an automatic-shutdown system which is completely pneumatic for use in locations where the use of electricity is considered hazardous. In this system, when the pen reaches the set point, the output air pressure from the instrument decreases. The controlled valve closes, and a small diaphragm valve in the air line from the instrument also closes. With the diaphragm connection of this valve on the downstream side of the valve, both valves will remain closed even though the pen on the instrument returns to a position below the set point. However, the valves can be reopened by manual operation of the reset valve which should be of the self-closing type. Similar systems using combinations of electrical control instruments and electrically operated valves have been used in nonhazardous locations.

Distillation equipment varies from small kettle stills to large continuous stills, and the instrumentation applied varies accordingly. Kettle-type stills require little control equipment. They are usually charged with a given quantity of material which then is heated until the volatile components are removed. Then the still is emptied. In such operations, the vapor temperature at the top of the still is the main guide in its operation. The vapor temperature may be simply recorded while the still operator manually controls the heating medium in accordance with his observations of the temperature record, or the temperature recorder may incorporate a control system automatically to control the heating medium or shut off the heating medium and open the discharge valve when a predetermined temperature is reached In some continuous-still operations, the feed is sufficiently uniform that efficient operation can be obtained with a flow-rate controller on the feed and a flow-rate controller on the steam supply, a temperature recorder on the vapor line, and a liquid-level controller regulating a valve in the discharge from the bottom.

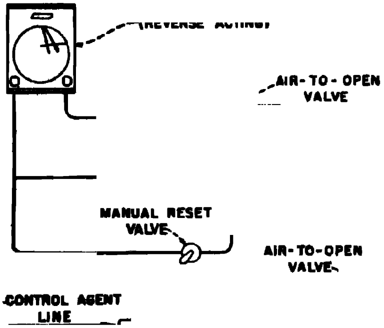

FIG. 10-67. Pneumatic safety shutdown system.

Figure 10-68 outlines the *instrumentation on a large fractionating column with a separate reboiler.* A flow-rate controller admits the feed to the column at a uniform rate. The feed could also be brought through a controlled heat exchanger so that it would enter the column at a constant temperature. A pressure controller regulates the release of vapor from the column to maintain a uniform back pressure. A temperature controller resets the control index of a flow controller on the steam line to the reboiler to maintain a uniform temperature of the vapor leaving the reboiler This method of controlling the steam eliminates variations due to fluctuations in steam pressure. A flow-rate controller on the reflux line regulates the return of condensate to the column. A level controller or the reflux accumulator governs t valve in the product line so that the demands for reflux will be met first. A mu tipoint instrument records the temperature of the vapor, the feed, the condensate, and the temperatures at several locations on the column. Variations of the above instrumentation of a fractionating column can be made to meet particular require

FIG. 10-68. Typical control system for continuous fractionating column.

ments. For example, the back pressure on a column can be controlled by regulating the flow of cooling water to the condenser. Also the steam pressure to the bottom of a column has been regulated from the pressure differential across the column to maintain a uniform rate of vapor up the column, and ratio controllers may be used to return a fixed percentage of the condensate to the column.

INSTRUMENTATION COSTS

Instrumentation of plant operations, especially where continuous processing is involved, has increased manyfold during the past decade or two. This increased usage of instruments and automatic controls is a result of several factors all intimately associated, directly or indirectly, with processing economies.

Instruments are rapidly becoming an integral consideration in the design of all processing plants, and the conception that indicating, recording, and controlling instruments are accessories "to be added later" is seldom encountered where new construction is involved. Consequently, instrumentation costs now represent a significant portion of the over-all investment in plant equipment, whereas in a past era, the expenditure for instrumentation was oftentimes placed in the realm of incidental costs.

It must be stressed that, while most plant designers and contractors recognize the factor of instrumentation at the outset of a project, they too often relegate the proposed expenditure for instrumentation to the tail end of their project budget thinking. Consequently, instrumentation costs often are underestimated, with resultant penalties to smooth and efficient process operation. Although only 5 per cent of the investment in a plant may be required for instrumentation, it is an extremely important 5 per cent and, if trimmed by only ½ per cent, the "apparent" savings will ultimately be reflected in one of several ways, including higher over-all costs and lower product quality.

A study of instrumentation costs not only is complicated by the great variety of plant operations and processes used, the basic instrumentation requirements of which vary widely, but also by the many methods of measurement and styles of instruments available to do a given job. A process temperature can be measured in one fashion, *e.g.*, by simple, low-cost glass-stem thermometers; on the other hand, where accurate, continuous, and automatic recording and controlling of temperatures are required, the instrument to do the job may logically be a self-balancing potentiometer incorporating carefully machined parts and electrical and electronic components, all mounted in a rugged case of attractive appearance for convenient mounting on a control panel. Obviously, instruments of the latter type, performing many more functions and assuming greater responsibilities, cost more. Over-all instrumentation costs have risen not only because more instruments are being used but also because the instruments themselves have become sophisticated and complex.

Tastes of the design engineer also greatly affect over-all instrumentation costs. There is a trend in the design of control rooms for large processing units toward more and more attractive appearance of instrument-panel boards and greater comfort and pleasing surroundings in the control room. Air conditioning, indirect lighting, soundproofing, and color dynamics in the control room are looked upon by some designers as luxury items of purely aesthetic value; other designers regard them as important contributing factors to long-term operating efficiency of the unit. Some designers are content to install pressure gauges on each pump or blower; other designers specify that these instruments all be incorporated on a central panel board in the pump room. The figures given in the table with this article are based upon average installations of the day. Where centralized control is not considered essential, possibly these figures will be a trifle high; where it is desired to take advantages of centralized control and an attractive and comfortable control room, the figures will be considerably lower. Thus, the factor of taste must be considered when making a cost estimate.

For use in making preconstruction instrumentation-cost estimates at a stage before the complete instrument and automatic-control layout is known, the percentage of total equipment cost required for instrumentation, as experienced by other similar processes, can be helpful. A very limited but recent survey of the chemical process industries divulges the figures presented in Table 10-2.

Instrumentation costs for the production of methanol intermediates, acetic acid recovery, polythene synthesis, manufacture of acrylic resin molding powder, and agricultural insecticide and fungicides are reported by one user to vary from 8 to 12 per cent of the investment in total installed equipment. Another user reports that the average instrumentation cost for 10 units making agricultural chemicals and plastics is 9.7 per cent. A progressive manufacturer of perfumes and cosmetics reports that instrument costs usually run between 5 and 10 per cent, but that on some processes, instrument costs run as high as 19 per cent. A textile manufacturer reports that the average mechanical operation in a textile mill, such as weaving and spinning, requires an investment in instrumentation of well under 1 per cent of the total plant-equipment investment. Large soap manufacturers report that instrumentation costs run between 2.2 and 3.2 per cent of the total investment in equipment. On a more complicated plant operated by a soap manufacturer, it is reported that the instrumentation costs are as high as 8.6 per cent. A processor of nonferrous ores and manufacturer of nonferrous salts reports that instrumentation costs of an electrolytic refining unit are approximately 1.02 per cent. A lime plant owned by this same processor has an investment of only 0.39 per cent in instrumentation.

Table 10-2. Installed Costs of Instruments as Percentages of Total Plant- and Process-equipment Costs

Process type	*Per cent of equipment cost*
Ethylene plants	4
Solvent-dewaxing units	3
Thermofor catalytic cracking units	3.4
Viscose making	2.9
Synthetic ammonia plants	3.2
Contact sulfuric acid plants	3
Nitric acid plants	2
Hydrochloric acid plants	1.9
Superphosphate plants	Negligible
Hydrofluoric acid alkylation units	5.7
Gas-recovery units	4.9
Styrene plants	4
Pharmaceutical plants	15
Soap plants	2 3 2
Electrolytic nonferrous metal refining	0.91
Lime plants	0.45
Manufacture of fluoride salts	1.1
Pulp mills	3
Textile mills	1.5

These wide variations in instrumentation-cost percentages are a result of many factors as discussed in the following paragraphs.

Numerous factors determine the percentage of the total investment in a process which must be allotted to instrumentation. Some of these factors are: (1) nature of unit operations making up process; (2) special items required because of corrosion, low flows, etc.; and (3) capacity vs. number of processing units. The fact that some industries are more instrument-minded and conscious of the many advantages which continuous measurements and automatic controls bring about also has an important bearing on comparative costs. Petroleum refiners and manufacturers of organic chemicals are outstanding in their appreciation of instrumentation, and hence they invest more capital in this direction. An important observation made over the past few years indicates that improvements and technical progress in processing go hand in hand with increased instrumentation.

Processes involving distillation are well known as heavy users of instruments. One fractionating tower, for example, may require a potentiometer to control column temperature by resetting the control index of a flow controller on the steam-supply line to the reboiler, a flow controller on the tower feed, a liquid-level controller or the tower bottoms, a flow controller on the reflux line, a liquid-level controller on the reflux accumulator, and integrating flowmeters on the product lines.

On the other hand, mixing, crushing, grinding, and filtering are operations which usually require only the simplest type of instrumentation. A superphosphate plant which involves principally crushing, grinding, leaching, mixing, and packing involves practically no instrumentation. Reflection on the figures given in Table 10-2 will bear out these conclusions.

Some operations require that more variables be controlled and more facts be known than do others. Logically, where temperature, pressure, pH, or other variables must be controlled within very narrow limits, the best in available instrumentation will be required. Where costs of steam and other mediums are extremely pertinent, numerous recording and indicating meters may be required.

It is not unusual for 50 per cent of the total investment in a pilot plant to be devoted to instruments and controls. Here temperatures and pressures and other variables are measured and recorded at a host of locations which normally would not be of interest in a large operating unit once it is developed.

Where corrosive materials are handled, equipment costs in general rise. Instruments and controls are no exception. The figure of 5.7 per cent for hydrofluoric acid alkylation given in Table 10-2, as compared with the other typical petroleum processes listed, is due in large part to special valves, protection for sensing elements, etc. Where small flows which cannot be handled in the smallest conventional control valves are encountered, more expensive valves of special construction must be used, upping the total instrumentation costs.

Although the capacity of one unit making a given substance may be three times the capacity of another unit making the same substance, the number of critical process variables which must be measured or controlled remains about the same. For example, about 4 per cent of the investment in a 20-ton-capacity contact sulfuric acid plant is for instrumentation. A 200-ton-capacity plant requires only 2 per cent investment in instrumentation. In increasing the capacity of a unit, the major increase in instrumentation costs is brought about by the greater cost for larger control valves, longer lengths of extension wire, connecting tubing, etc., and is not markedly affected by requirements for a larger number of individual instruments.

PIPE, VALVES, AND FITTINGS FOR NORMAL AND HIGH PRESSURES

BY C. A. DOPP

Directing Engineer, Valve and Fitting Engineering Department, Crane Company

AND E. C. PETRIE

Manager, Engineering and Research Division, Crane Company

Pipe, valves, and fittings are used in every industry to convey fluids from one point to another. These fluids may be in a gaseous state, a liquid form, semisolid, abrasive, and/or corrosive; they may be flowing under low-pressure conditions, high pressure, and at low or high velocities. Each of these and other manifold variables make the proper selection of the most suitable piping material, the valve which will perform most satisfactorily, or the fitting which will produce the utmost in economy and service a problem which can be dealt with only by one having sufficient information regarding the performance of pipe, valves, and fittings under the service conditions which are likely to be encountered.

In the design and selection of piping materials for service conditions ranging from the average home plumbing installation to the h-p power plant, careful study must be given to the individual requirements to provide a basis for the selection of the proper equipment.

The primary purpose of this subsection is to present information which can be used as a guide by the designer in selecting the product most suitable for the many service conditions encountered in the various industries. While it is true that there are many codes, standards, and manufacturers' catalogues which can be used to some degree for this purpose, the basic reasoning behind the adoption of certain types of products may not be readily available. It must be understood, however, that no product should be used which is definitely legislated against by these codes or standards and that manufacturers' recommendations should be followed.

PIPE

The most prevalent type of product used in all piping systems is "pipe." The selection of the size, material, and class of pipe for a particular service condition is dependent upon several factors among which are pressure, temperature, corrosion, availability, etc.

PIPE MATERIALS

The pipe material is generally selected on the basis of the requirements set up in various codes and standards which refer in the majority of cases to specifications established by the American Society of Testing Materials. Other widely used specifications are those published by the Navy Department, the American Petroleum Institute, and the United States Government. A partial list of piping materials and the corresponding specification reference is given in Table 11-1.

Some of the more important piping materials and their specific characteristics are as follows:

Carbon-steel Pipe. Carbon-steel pipe derives its distinctive properties chiefly from the amount of carbon which it contains. The basic material used in the production of carbon-steel pipe is generally produced either by the open-hearth, electric-furnace, or the acid-Bessemer process. In ordering the pipe for fabrication, open-hearth-process pipe is generally specified because of its superior forming qualities.

Butt-welded carbon-steel pipe is available in sizes from $\frac{1}{8}$ to 3 in. inclusive, lap-welded pipe is available in $1\frac{1}{4}$-in. sizes and larger. Both types are available in standard and extra-strong thicknesses. Carbon-steel pipe is manufactured to conform with numerous ASTM specifications, three of which are commonly used for fabricating.

Table 11-1*

Materials, pipe, and tubing	*Specification*
Brass and copper	
Copper pipe, standard sizes	**ASTM B42**
Red brass pipe, standard sizes	**ASTM B43**
Seamless copper tubing, bright annealed	**ASTM B68**
Seamless copper tubes	**ASTM B75**
Copper water tube	**ASTM B88**
Copper and copper-alloy seamless condenser tubes and ferrule stock	**ASTM B111**
Cast iron	
Cast-iron pit-cast pipe for water or other liquids	**ASA A21.2 and** **ASTM A44**
Pipe, water, cast iron (bell and spigot)	**FSB WW-P-421**
Mechanical joint cast iron pipe	**CIPRA**
Wrought iron	
Welded wrought iron pipe	**ASTM A72**
Spiral welded steel or iron pipe	**ASTM A211**
Casing, drill pipe, and tubing	**API 5-A**
Line pipe	**API-5-L**
Steel	
Welded and seamless steel pipe	**ASTM A53**
Lap welded and seamless steel and lap welded iron boiler tubes	**ASTM A83**
Forged or rolled steel pipe flanges, forged fittings, and valves and parts for high temperature service (material for forged and bored carbon steel pipe)	**ASTM A105**
Seamless carbon steel pipe for high temperature service	**ASTM A106**
Black and hot dipped zinc coated (galvanized) welded and seamless steel pipe for ordinary uses	**ASTM A120**
Electric fusion welded steel pipe (sizes 30 in. and over)	**ASTM A134**
Electric resistance welded steel pipe	**ASTM A135**
Electric fusion welded steel pipe (sizes 8 in. to but not including 30 in.)	**ASTM A139**
Electric fusion welded steel pipe for high temperature and h.p. service	**ASTM A155**
Seamless alloy steel pipe for high temperature service	**ASTM A158**
Electric resistance welded steel and open hearth iron boiler tubes	**ASTM A178**
Seamless cold drawn low carbon steel heat-exchanger and condenser tubes	**ASTM A179**
Forged or rolled alloy steel pipe flanges, forged fittings, and valves and parts for high temperature service (material for forged and bored alloy steel pipe)	**ASTM A182**
Seamless steel boiler tubes for h.p. service	**ASTM A192**
Seamless carbon molybdenum alloy steel pipe for high temperature service	**ASTM A206**
Medium carbon seamless steel boiler and superheater tubes	**ASTM A210**
Spiral welded steel or iron pipe	**ASTM A211**
Seamless alloy steel boiler and superheater tubes	**ASTM A213**
Electric resistance welded steel heat exchanger and condenser tubes	**ASTM A214**
Electric resistance welded steel boiler and superheater tubes for h.p. service	**ASTM A226**
Atomic hydrogen arc welded and electric resistance welded alloy steel boiler and superheater tubes	**ASTM A249**
Copper brazed steel tubing	**ASTM A254**
Casing, drill pipe, and tubing	**API 5 A**
Line pipe	**API 5-L**
Seamless and welded ferritic stainless steel tubing for general service	**ASTM A268**
Seamless and welded austenitic stainless steel tubing for general service	**ASTM A269**
Seamless austenitic chromium nickel steel still tubes for refinery service	**ASTM A271**
Seamless chrome molybdenum alloy steel pipe for service at high temperatures	**ASTM A280**

* Published in ASA Code for Pressure Piping, Supplement No. 2, April 1947.

ASTM A120 Specification for Black and Hot-dipped Zinc-coated (*Galvanized*) *Welded and Seamless Steel Pipe for Ordinary Uses.* ASTM A120 pipe might be called the "garden" variety of pipe since it is used extensively for general piping purposes. These ordinary uses include those for low-pressure domestic service, small-size low-pressure water installations, and gas lines. A120 is not suitable, however, for close bending or for high-temperature service.

The steel used for this pipe is made by the open-hearth, electric-furnace, or the acid-Bessemer process and is of soft weldable quality. If galvanized pipe is desired, the coating inside and outside is applied by the hot-dip process, and the weight of the coating is listed in ounces per square foot. Specimens of each lot of pipe are selected and subjected to tests that measure their coating weight, pipe weight, hydrostatic strength, weld strength, and diameter and wall thickness. A120 pipe lengths are usually cut in the 16- to 22-ft range for standard-weight pipe. Specifications are also listed for workmanship and finish required for this grade of pipe which is stamped or stenciled to show the manufacturer, the length, and the ASTM Specification A120.

ASTM A53 Specification for Welded and Seamless Steel Pipe. ASTM A53 pipe is manufactured as black or hot-dipped galvanized pipe and might be called a medium-grade pipe. Pipe complying with these specifications may be used for coiling, bending, flanging, or other specified special purposes. The steel for A53 is made by the same process as that used for A120 with the exception that electric-resistance-welded pipe for the smaller sizes of ⅛ and ¼ in. in diameter is made from open-hearth steel. The chemical content for this pipe steel is specified, and samples from each lot of 500 lengths are checked against the specifications. The tensile strength as well as the flattening and bending properties of the pipe are checked. Following the hydrostatic test, the pipe is checked for weight, workmanship, finish, marking, and final inspection.

The Code for Pressure Piping limits the use of A53 to a maximum steam pressure of 400 lb and a maximum temperature of 750°F. Other codes differ in their specified use for A53.

ASTM A106 Specification for Seamless Carbon-steel Pipe for High-temperature Service. The steel used for A106 pipe, which is specified as grade A or grade B, is killed steel made by the open-hearth or the electric-furnace process. The chemical composition and the physical properties are carefully specified and presented in table form. Test specimens are used to determine the bending and flattening properties of the pipe, and unless otherwise specified, each length of pipe is hydrostatically pressure-tested. After checking the weight, wall thickness, diameter, finish, and over-all workmanship, the pipe is marked and inspected. A106 pipe is used for high-pressure and high-temperature work and should be suitable for bending, flanging, lapping, and similar forming operations. The A106 specifications are rigid, and the manufacturing tolerances which are specified are closely followed by the producer.

Alloy-steel Pipe. The term "alloy-steel pipe" is meant to apply to any tubular steel product which differs from carbon steel by the addition of one or more alloying metals to which it owes its distinctive properties. The basic materials for the manufacture of alloy pipe are made by the open-hearth or electric-furnace process. Most of the alloy-steel pipe is made by the seamless process, although some high-alloy varieties are produced as welded pipe. In the sizes up to 1½ in. the pipe is cold-drawn; in sizes from 1½ to 10 in. it is either hot-finished or cold-drawn; and in sizes above 10 in. it is hot-finished. Alloy-steel pipe is normally classified by schedule number or wall thickness.

In recent years steam temperatures have exceeded the limits for which carbon-steel pipe is suitable. This has naturally resulted in the more extensive use of alloy-steel piping. In power-plant work involving temperatures up to 1000°F, carbon-molybdenum pipe has found wide application. Basically this material is a low-carbon (0.10 to 0.20 per cent) silicon-killed steel to which molybdenum (0.45 to 0.65) per cent is added. This small quantity of molybdenum gives the material superior creep resistance at temperatures up to 1000°F. At this writing certain specifications call for the addition of 0.5 to 1.0 per cent chromium to resist graphitization of carbon-molybdenum piping at welded joints which results from service under high temperature.

ASTM A206 Specification for Seamless Carbon-molybdenum Alloy-steel Pipe for High-temperature Service (Tentative). A206 seamless carbon-molybdenum alloy-steel pipe for high-temperature service is made of steel selected for its high-temperature properties, weldability, and general stability under severe working conditions. This steel is made either by the open-hearth or the electric-furnace process, with the grain size carefully checked to meet the specified limits. After the finishing process is completed, the pipe is annealed. The chemical composition and the tensile properties are tabulated for quick reference. When the purchaser so requests, a photomicrograph at 100 diameters, taken from a specimen cut, is furnished by the manufacturer. As specified by the code, the use of A206 is, at the present time, quite rigidly controlled.

ASTM A158 Specification for Seamless Alloy-steel Pipe for High-temperature Service

All dimensions are given in inches

The decimal thicknesses listed for the respective pipe sizes represent their nominal or average wall dimensions For tolerances on wall thicknesses see appropriate material specification

Thicknesses shown in boldface type in Schedules 30 and 40 are identical with thicknesses for standard weight pipe in former lists those in Schedules 60 and 80 are identical with thicknesses for extra strong pipe in former lists

The schedule numbers indicate approximate values of the expression $1\,000 \times P/S$

Owing to a necessary departure from the old standard weight and extra strong thicknesses in the 12-in size in Schedules 40 and 60 the new thicknesses are not as yet stocked by all manufacturers and jobbers Hence where agreeable to the purchaser and suitable for the service conditions the old standard weight 0.375-in wall pipe corresponding to a $1\,000\,P/S$ value of 37.7 is still available and can be substituted for the 0.406 in wall and the old extra strong 0.500-in. wall pipe corresponding to a $1{,}000\,P/S$ value of 55 can be substituted for the 0.562 in wall

(*Tentative*) ASTM A158 pipe covers several varieties of ferritic and austenitic seamless pipe and is applicable to services where the metal temperatures are high or where corrosion may be a factor These steels are characterized by their high-temperature properties, weldability, corrosive resistance, and general stability at the working temperatures They are made either by the open-hearth or electric-furnace process The heat-treatment to be used is carefully followed, and the tensile-strength limits are tabulated as a means of ready reference. Bending, flattening, and hydrostatic tests are made to check the quality of the product

The petroleum industry is a large user of alloy-steel piping Most of the low-alloy and 4 to 6 per cent chrome varieties of pipe were developed to combat the extremely corrosive conditions encountered in modern petroleum-refining processes Many of the cracking processes involve extreme temperatures, thus necessitating the use of higher alloy steels

The relatively high cost of alloy-steel pipe limits its application to those installations involving extreme temperatures and having severe corrosion conditions and where carbon steel is not found to be entirely satisfactory

* Weights are given in pounds per linear foot and are for pipe with plain ends except for sizes which are commercially available with threads and couplings for which both weights are listed.

† Weight for line pipe with couplings are slightly greater than shown in Schedules 30 and 40 and may be found in API Specification 5-L. Weights shown in boldface type in Schedules 30 and 40 are identical with weights for standard-weight pipe in former lists; those in Schedules 60 and 80 are identical with weights for extra-strong pipe in former lists.

The schedule numbers indicate approximate values of the expression 1,000 × P/S.

Genuine Wrought-iron Pipe. The basic material used in the manufacture of genuine wrought-iron pipe is made from pig-puddled or processed wrought iron and is free from any admixture of iron scrap or steel. Wrought iron is defined as a ferrous material aggregated from a solidifying mass of pasty particles of highly refined iron with which, without subsequent fusion or chemical relationship, is incorporated a minutely and uniformly distributed quantity of slag. The durability of wrought iron when subject to general corrosive conditions is attributed to the siliceous slag fibers imbedded in the base metal. Wrought-iron pipe finds wide application in plumbing, water, and underground pipe lines where certain corrosive conditions exist.

This pipe is produced in butt-welded and lap-welded form. Sizes from ⅛ to 2 in., inclusive, are produced in the form of butt-welded pipe; sizes from 1¼ to 12 in. inclusive, are produced by the lap-welded process; sizes from 14 to 24 in. OD are either hammer-welded or fusion-welded. In the main genuine wrought-iron pipe is most used in those sizes 12 in. in diameter or smaller.

Genuine wrought-iron pipe may be obtained in standard, extra-strong, and double extra-strong thicknesses and is manufactured to conform to ASTM A72 specification for general usage, coiling, bending, flanging, and other special purposes. Although this material is more expensive than carbon steel, the producers claim that its resistance to corrosion offsets any difference in cost when the length of service is considered.

Toncan Iron Pipe; Copper-bearing Steel Pipe. In addition to carbon steel, occasional use is made of copper-bearing steel pipe or copper-molybdenum iron (Toncan) pipe. Copper-bearing steel is steel with an addition of 0.20 to 0.35 per cent copper. Toncan iron is open-hearth iron containing 0.10 per cent copper and 0.57 per cent molybdenum.

Brass and Copper Pipe. The three basic materials of this group consist of yellow brass, having an approximate composition of 67 per cent copper and 33 per cent zinc; red brass, which has an approximate composition of 85 per cent copper and 15 per cent zinc; and copper pipe, which is manufactured close to a 99.9 per cent copper

analysis. The pipe is seamless and is formed by cupping and drawing or by extrusion.

Yellow brass is suitable for most general water installations and is cheaper than either red brass or copper. Red brass, while more expensive than yellow brass, is easier to fabricate and, owing to its smaller zinc content, does not deteriorate so rapidly for severely corrosive water service. On the other hand, yellow brass has been found to be subject to corrosion due to dezincification.

Copper and brass are extensively used for handling waters, acids, alkalies, and other generally corrosive fluids.

Pipe Dimensions

Steel Pipe. Since steel pipe must be suitable for a wide range of services with respect to pressure, temperature, corrosion, and the like, it is produced in a variety of wall thicknesses and different weights for each of the various sizes. As a general rule, particularly in the case of carbon steel, pipe is classified by the terms standard, extra strong, and double extra strong. A more suitable method, which is being more universally applied particularly to alloy-steel pipe, has been developed by the ASA, *viz.*, the classification of pipe by schedule number (see Tables 11-2 to 11-5).

Pressure Rating for Steel Pipe. For pressure rating for steel pipe, refer to ASA Code for Pressure Piping, ASME Boiler Construction Code, or any code or standard applying to a specific application.

Expansion of Piping Materials. For expansion of piping materials, see Table 11-6.

VALVES

Valves are among the most important of all control instruments used in industry. Their function is to control and stop the flow of water, oil, gas, steam, air, chemicals, and in fact, any liquid or gas conveyed from place to place. Their selection for any particular service condition can be best accomplished by one who is thoroughly acquainted with their individual characteristics.

Classification of Valves by Material

There are three basic materials from which the principal parts of the great majority of valves are made. These are brass, iron, and steel. Each has its particular purpose in valve design. All these materials are made in a large variety of compositions having varying strengths and resistance to the effect of corrosion and temperature.

Brass. Brass is used extensively for bodies and bonnets of valves where resistance to corrosion by liquids or gases is desired. It is a satisfactory material to resist the corrosive action of most water and atmospheric conditions and can be used for most normal pressure and temperature conditions. It can be cast or forged and is reasonably easy to machine. Because it is much higher in cost than cast iron, its use usually has been confined to sizes 3 in. and smaller. Many large brass valves are used, however, to resist the corrosive action of sea water. Some of the specifications generally referred to for brass valves are

ASTM B62 Specification for Composition Brass or Ounce Metal Castings. ASTM B62 is widely used for valves rated as high as 150 lb steam pressure. It is limited by most codes to a maximum temperature of 400°F.

ASTM B61 Specification for Steam or Valve Bronze Castings. A brass used by the majority of manufacturers for valves having ratings higher than 150 lb steam is covered by the above specification. While some codes limit the use of this material to 500°F, most manufacturers recommend it for as high as 550°F.

Cast Iron. Cast iron is generally used for valve sizes 2 in. and larger except where a more ductile or more corrosion-resistant material is necessary. Although cast iron is used for reasonably high pressures, the metal sections must be made quite heavy because of its relatively low physical properties which consequently makes it more difficult to obtain sound pressure-tight castings. Its use, therefore, is generally restricted to pressures 500 lb and lower, particularly in sizes above 12 in. Codes in general limit the use of cast iron to a maximum temperature of 450°F. Cast iron for valves is covered by ASTM Specification A126.

Cast Steel and Forged Steel. Cast steel and forged steel are the accepted materials in valve bodies and bonnets for extremely high pressures, particularly when used in services where temperatures are in excess of 500°F. Its high strength, high ductility, and shock resistance, as well as resistance to the effect of high temperatures, make steel an extremely important material in the valve industry. The many different compositions and alloys, ranging from carbon steel to stainless and high-strength steels, make this material applicable for use in valves of all sizes, shapes, and designs.

Classification of Valves by Types

The basic types of valves are globe, gate, and check. There are many variations in the design of each type which make each one particularly adaptable to a specific use. In a piping system there are a multitude of requirements which must be considered when the type of valve is to be selected.

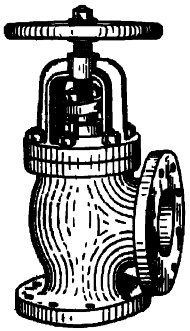

FIG. 11-1. Angle valve.

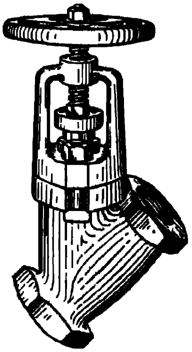

FIG. 11-2. Y-pattern globe valve.

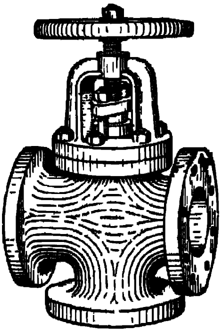

FIG. 11-3. Cross valve.

Globe Valves. The name "globe" probably originated because the common type of globe-valve body was globular in shape. The term globe, however, has for years been generally accepted as applied to the fundamental principle of plugging or stopping off a valve seat. For this reason, the term "globe type" has become quite common as it frequently applies to valves having shapes differing from the original globe valve, such as the angle, Y pattern, or cross.

The three globe-type valves illustrated in Figs. 11-1, 11-2, and 11-3 operate on the same principle as a regular globe valve. As shown in the cuts, any valve in which the closing and opening of the port through the valve seat is accomplished by forcing a "disc" down against the seat or into the seat opening to close it completely and where to open it the disc must be withdrawn is considered to be a "globe type." The force to actuate the disc is applied through the valve "stem" either by means of the stem threads or other actuating members such as levers, operating cylinders, toggle, etc.

Globe-type valves have always been preferred for throttling service, as they are easily controlled, but as explained hereinafter, the plug-type metal-disc design has given most satisfactory service.

Method of Operation. In globe valves, two common design principles are applied to the operating mechanism. One of these is the inside-screw rising stem (Fig. 11-4). In this type, the stem thread rotates in a corresponding or mating thread inside the bonnet so that, as the stem rises or lowers, it revolves as it moves the discs. Owing to the fact that the operating threads are exposed to the fluid within the valve, this design should not be used if the threads are likely to be seriously damaged by the fluid. For example, if the fluid contains an abrasive substance, excessive wear will quite likely occur in the stem threads and thus cause difficult operation.

In such cases a valve with an external operating mechanism such as the outside-screw and yoke (OS and Y) rising stem (Fig 11-5) should be used This type is generally specified in connection with larger sized valves. In this valve the stem thread rotates in a corresponding thread in the upper hub of the yoke. The stem itself also rises and lowers, thereby causing the disc to move up or down. It will be noted that the stem threads in this valve are not exposed to the fluid inside the valve.

There are also numerous special operating means such as the automatic-closing type of sliding stem as shown in Fig. 11-6. Globe-type valves are also made with

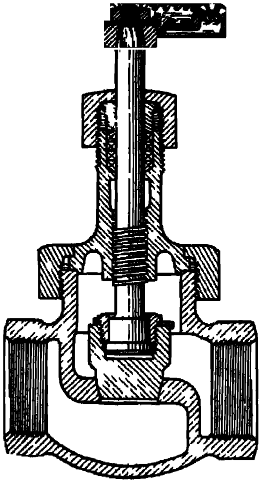

FIG. 11-4. Inside-screw, rising-stem globe valve.

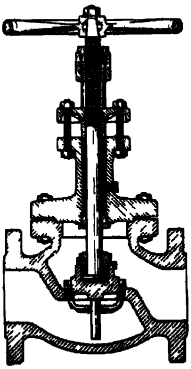

FIG. 11-5. Outside-screw and yoke (OS and Y) globe valve.

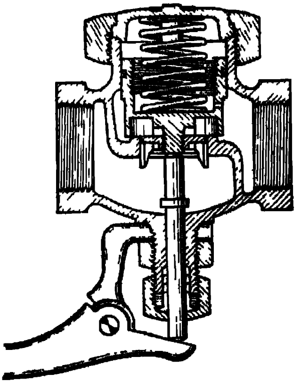

FIG. 11-6. Quick-opening sliding-stem globe valve.

special operating means such as gearing, cylinder operation, motor operation, etc. For all these the operating mechanism within the valve proper must be designed to suit the particular operating means.

Seat and Disc. The most important features of any valve, as far as service and tightness are concerned, are the material, design, and workmanship of the seat and disc. Briefly, the three designs of globe-type valves now in most common use are

1. Metal disc—narrow conical seat
2. Plug disc
3. Composition disc

There are many other special seat designs, but the general field is quite well covered by these three. Each has its advantages and each serves a useful purpose in industry.

Metal Disc—Narrow Conical Seat. The metal disc with a narrow conical seat usually has a ball-shaped surface on the disc, a conical flat seating surface in the body, and is generally referred to as the conventional design of globe valve. Figures 11-7 and 11-8 illustrate this design of seat and disc as applied to brass and steel globe valves.

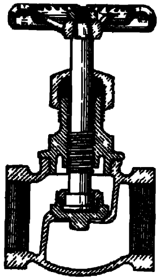

FIG. 11-7. Brass globe valve with ball disc and conical seat.

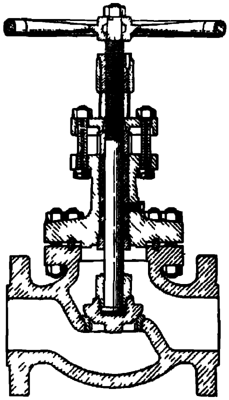

FIG. 11-8. Steel globe valve with ball disc and conical seat.

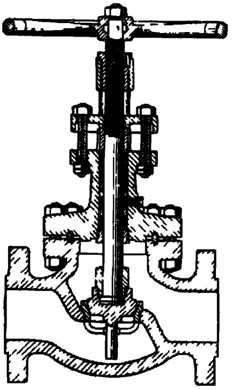

FIG. 11-9. Globe valve with plug-type disc

Because of the line bearing obtained in seating, this design is easily made tight, can be refaced or reground readily, and is adaptable to many types of services. Because operators have found that this type of seat provides an excellent means for removing coke, it is often specified for high-temperature oil service. Coke forms on metal surfaces in lines carrying high-temperature oil vapor. This hard brittle coating on the seating surfaces is generally not uniform in thickness and would soon lead to leaky valves. Because of the excessively high loading on the seating surface, the coke will crack when the operator closes the valve tightly. The valve is then opened slightly permitting a high-velocity flow across the seat, which action washes away the coke particles. This procedure is generally repeated several times when the valve is closed, particularly if the valve has been in service with the disc in the open position for a relatively long period.

The principal disadvantage of this type of seat is that very hard dirt or foreign matter may dent the seating surface, causing leakage. The result of such leakage is the inevitable wire-drawing action, which will destroy the seat in a very short time. Even though the dirt may not be hard enough to cut into the metal, if it holds the disc away from its seat and is allowed to remain in this position, the flow through the valve will cut the seat by wire-drawing action. When any valve fails to seat properly, it should be opened part way again and allowed to blow a short time. This, if repeated several times, will sometimes remove the obstruction and materially increase the life of the valve.

Plug Disc. The plug-type disc design has gained in popularity in recent years because of its ability to (1) throttle flow more effectively than other designs and (2) resist the wire-drawing action of high-velocity flow. This construction as illustrated in Fig. 11-9 comprises a plug-type disc and mating seat which produces

1. A gradual increase or decrease in the distance between the seat and disc surfaces when the valve is slowly opened or closed. This causes a gradual change in flow area thereby providing for close throttling control.

2. A wide contact area between disc and seat surfaces. In this manner the effect of wire drawing is greatly minimized as cutting always starts at outer edges of a bearing surface. In addition, any indentations in the seat caused by hard particles of foreign matter are unlikely to extend across the entire disc or seat surfaces and, therefore, are not apt to cause leakage.

If top-grade seating materials are used in this design, it is extremely difficult to surpass the service life of a plug-disc globe valve.

Composition Disc. The composition-disc design (Fig. 11-10) has been widely used for many services because of the ease with which a disc can be replaced. Its principle advantages are: (1) It requires less power to seat tight than a metal-disc valve. (2) Disc can be renewed with little effort. (3) It is less likely to be damaged by dirt or foreign matter than the metal disc with narrow seat. Dirt will imbed itself into the disc, and the valve will remain tight unless the dirt particle is exceptionally large. (4) By the use of different discs, the valve can be made suitable for different services such as steam, water, air, or gas.

For the most part, the use of composition discs has been confined to small sizes and for service conditions not to exceed 450°F because of the difficulties of obtaining suitable compositions for larger sizes and higher temperatures. A composition-disc valve should never be used for throttling as it may not give satisfactory service. Composition discs generally break down more quickly than metal discs when throttled, and on steam service a composition disc will expand enough to effect the steam flow if throttled closely.

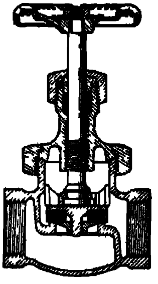

FIG. 11-10. Globe valve with composition disc.

Although a composition-disc valve is a great convenience when used in the proper service, it requires reasonable attention the same as any other mechanical device. If a disc has been in service long enough to cut out or leak for any reason, it must be replaced within a reasonable time or the valve seat will be damaged by wire drawing. It is a wise precaution to examine the seat before replacing the disc and, if it has been damaged, to take a cut off the seating surface with a reseating tool before placing the valve back in service.

Proper Installation of Globe-type Valves. There has always been a difference of opinion as to whether a globe-type valve should be installed in the line with the inlet pressure acting under the disc or above the disc. Obviously, if the pressure is under the disc, the greatest force is required at the end of the closing operation to make the seat tight. If the pressure is above the disc, the greatest force is required at the start of the opening operation to pull the disc away from the seat. In either of these operations the force must overcome the full pressure per square inch multiplied by the area of the disc.

Let us assume that steam pressure is acting under the disc when the valve is closed. At the time of closure the pressure on the outlet side will be dissipated through whatever equipment the line is feeding. As the pressure on the outlet decreases, the temperature will also decrease. The stem which has been partly within the steam flow will cool and contract. Condensation in the line is likely to flow back into the valve submerging the stem and further cooling and contracting it. Since it is the stem which holds the disc tight against the seat, the contraction will decrease that load. Under these conditions the pressure under the disc will tend to force the disc away from the seat and may cause leakage.

Let us now assume that the steam pressure is acting above the disc when the valve is closed. The stem is still subjected to full steam temperature, and there is no relaxation of load. It is, of course, possible that condensate may build up in the valve body and cool the stem. If that happens, the stem would contract as in the former case, but the pressure acting above the disc will tend to hold it against the seat. This is possible because there is a certain amount of lost motion between the stem thread and its mating thread and also in the disc-stem assembly.

On high pressures it is easier to make a globe valve tight with the pressure above the disc than with the pressure under the disc.

From the above it can be seen that the preferred position for a globe valve in a steam line is to have the pressure above the disc. This method of installation, however, may be undesirable in some specific cases. No matter how well a valve may be designed or built, there is always a possibility that the disc might become loose from the end of the stem. If that should occur in a boiler feed line, for example, and the pressure were above the disc, the disc would close the valve as in a check valve, and it would be impossible to get water into the boiler.

A good rule to follow is "If it would be dangerous to have the valve close (in the event of a disc becoming loose from the stem), the inlet pressure should be under the disc." Under most other conditions globe valves should be installed with pressure above the disc. One exception to this is the composition-disc globe valve. Experience has shown that a composition disc will last considerably longer with the pressure acting under the disc than with the pressure above the disc. The resiliency of the disc is in most cases sufficient to overcome any tendency for the stem to contract and cause leakage.

Gate Valves. The term "gate" as applied to valves refers to that type of valve in which the port is closed by a flat-faced disc sliding at right angles over the seat port to close it. Because of the nature of this means of closing, it is quite difficult to control flow by throttling, particularly if it is necessary to set the valve to deliver a definite volume of fluid. It is also objectionable to use a gate valve for throttling for other reasons. When the disc is in the partly open position, the seat faces are so close to each other that wire drawing is bound to result and cause damage to the seats. In the double-disc type, because the disc assembly consists of two or more parts, these parts are likely to vibrate and wear out rapidly. For these reasons a gate valve should preferably be kept either tight shut or wide open.

One of the principal advantages of the gate valve is the clear unobstructed flow opening which results in a very low pressure drop through the valve. This is the principal reason why gate valves are so generally used in liquid lines and in large h-p steam lines.

Methods of Operation. The four standard methods of operation used in gate valves are as follows:

1. Outside screw and yoke (OS and Y) (Fig. 11-11)
2. Inside screw, nonrising stem (Fig. 11-12)
3. Inside screw, rising stem (Fig. 11-13)
4. Sliding stem—quick opening (Fig. 11-14)

The outside-screw and yoke design shown in Fig. 11-11 is made in either the solid-wedge or double-disc design and in brass, iron, and steel. It has several important features.

1. The stem is nonturning, rises through the yoke sleeve which is revolved in the upper hub of the yoke by the wheel, and supplies a positive indication of the position of the disc.

2. Because the threads on the stem are outside the valve, they are not exposed to the wear often resulting from abrasives carried in the fluid. The stem threads can very easily be greased and their life materially increased. This practice is strongly recommended.

3. Many large valves are regularly made with ball-bearing yoke sleeves. This practically eliminates the excessive friction on the yoke-sleeve thrust collars.

The inside-screw nonrising-stem design shown in Fig. 11-12 is common to either brass or iron gate valves but is seldom used in steel. Its principal features are

1. Requires much less headroom than the OS and Y design.

2. The stem which revolves to open or close the valves does not rise since it is held in place by the collar enclosed in the top of the bonnet and will give less trouble from stuffing-box leakage than any other type of stem action.

3. The stem threads which screw into the disc hub, thus raising or lowering the disc, are always exposed to the fluid within the valve. This can be an advantage if the fluid has lubricating qualities and does not contain abrasive matter, but in the latter case the threads are subject to severe wear and possible jamming or sticking.

Valves of the inside-screw nonrising design should not be used on high-temperature service because of the danger of uneven expansion of the parts causing binding of the threads and resulting in a galling action. This is the principal reason why large iron nonrising-stem valves are not often used for steam service, and large steel valves are seldom made in this design.

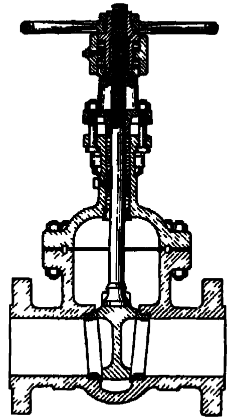

Fig. 11-11. Outside-screw and yoke (OS and Y) gate valve

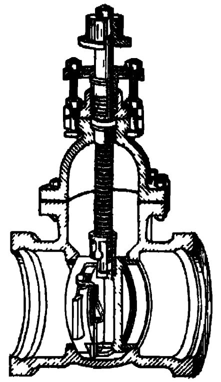

Fig. 11-12. Inside-screw, nonrising-stem gate valve.

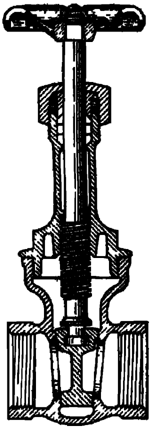

Fig. 11-13 Inside-screw, rising-stem gate valve.

The inside-screw rising-stem valve shown in Fig. 11-13 is seldom used except in small brass valves. In this design the stem rises and turns at the same time as the stem threads screw into a mating thread inside the bonnet. Its principal features are

1. The stem acts as an indicator of the position of the disc as it is raised or lowered.

2. It makes for a more compact small valve than the OS and Y as the need for a yoke is eliminated

3 Although these inside screw threads are subject to cutting action by any abrasive material in the line fluid, they give comparatively little trouble from this source on small valves.

The sliding-stem quick-opening design shown in Fig. 11-14 has the following features:

1. The stem slides up and down through the stuffing box and is actuated by a lever. It is intended only for special service where the flow must be cut off or on very quickly.

2. In the design of valve shown, the lever action is so designed that the maximum power necessary to close or open the disc is exerted at the point where the disc is in the closed position. As the valve is opened, the effective leverage is automatically reduced, and the speed of motion is increased, as it requires much less force to move the disc when it moves above the halfway-open point.

3. It should be remembered that no quick-opening valve should ever be used on water, oil, or other noncompressible fluid unless proper provision has been made in the line to prevent shock or water hammer. This is generally accomplished by the use of air chambers.

Disc Design. There are two basic designs of gate-valve discs in common use at the present time:

1. The wedge-disc design
2. The double-disc design

Wedge Disc. One of the best known disc designs is the solid wedge shown in Fig. 11-15. This design has been used in brass, iron, and steel gate valves for a great many years and with excellent results. Its principle of operation is quite obvious; the tapered wedge is driven in between the corresponding tapered seats, exerting an exceedingly high loading on the seat faces to hold tight against pressure. As the disc is withdrawn from the body seats, guided on the vertical center line of the body by a guide rib on each side, the disc faces are automatically withdrawn from the body seats because of the taper, and as a result the seat faces do not drag over each other after the fluid has started to flow. This prevents undue wear on the seat faces.

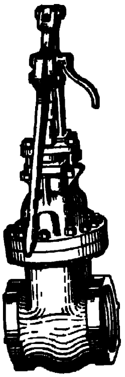

Fig. 11-14. Quick-opening, sliding-stem gate valve.

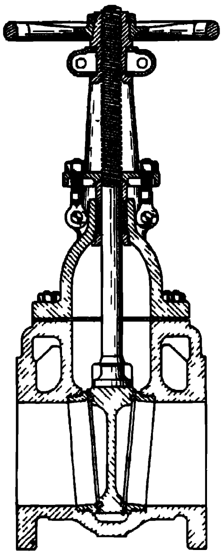

Fig. 11-15. Solid-wedge-disc gate valve.

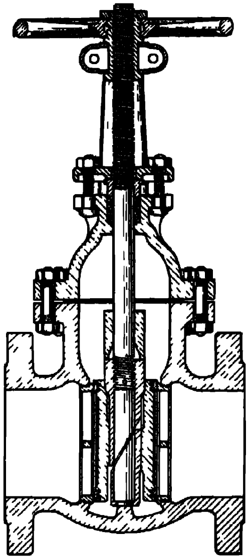

Fig. 11-16 Double-disc, parallel-seat gate valve.

The solid-wedge disc will perform satisfactorily in almost any service, such as water, air, gas, steam, or oil.

The advent of extremely high temperatures in power-plant service has produced a peculiar problem. When a solid-wedge disc is heated by superheated steam and then closed tightly and the valve allowed to cool, the disc may be held so tightly in the body that it is sometimes impossible to open the valve. Exhaustive testing has disclosed that, when the flow through an open valve causes heating of the parts, the disc which is in the bonnet is not heated to so high a temperature as the body of the valve and therefore does not expand so much as the body. This being the case, when the valve is closed and permitted to cool, the body contracts more than the disc thereby pinching it between the body seats. A steel disc of the flexible type has been developed which has sufficient spring to overcome this pinching action and therefore can be opened with comparative ease.

Double Disc. The double parallel disc, shown in Fig. 11-16, also is very popular. In this design the disc face drags over the seat face on the outlet side, and these two faces are held together by the pressure during the full travel of the valve This action has a tendency to wipe the seat clean, but in so doing, it accelerates wear and generally makes the valve harder to operate with high pressure against the disc. When the valve closes, the wedges between the two discs are stopped in the bottom of the body, causing the wedging surfaces to force the discs tightly against the body seats. There are various designs of wedging mechanisms for these discs, but they all operate on the same general principle.

Valves with double parallel seats are most commonly used in water-works lines and in pipe lines for cold oil and gas. Their use is insisted upon by many engineers owing probably to the fact that they are more easily repaired than the taper wedge-disc valves and also because their use in water works and pipe lines is traditional.

Check Valves. Check valves, which are designed to permit fluid flow in one direction only, fall into two general groups commonly known as swing check and lift check. Their purpose is extremely important to proper functioning of any piping system because of their quick automatic action and their sensitiveness to changes in flow conditions. Further, they will prevent dangerous backflow in a line when two or more fluids are being supplied to a common point at different pressures. Check valves might well be called "safety-first" valves.

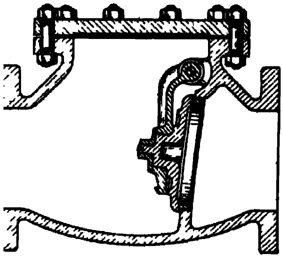

Fig. 11-17. Swing check valve.

Being automatic in action, check valves are subjected to greater abuse than are manually operated valves. Operators rely on the performance of their automatic features without giving any particular attention to periodic inspection. In addition, automatic action means that discs move back and forth with every fluctuation of flow and pressure and that this movement of the disc is not limited from one end of its travel to the other. It should be remembered that the only thing that makes a check valve tight when closed is the action of the pressure against the disc in the outlet end of the valve. The full line pressure is seldom available to accomplish this because the only effective holding power is the difference between the pressure on the outlet side and that on the inlet side. Although the slightest pressure differential will cause the valve to close, it requires a reasonable difference to hold the disc pressure-tight. As a result, a check valve is one of the most difficult valves to make and keep tight. The higher the pressure differential, the tighter the valve will be. These points are important and should be kept in mind when evaluating check valves in terms of service.

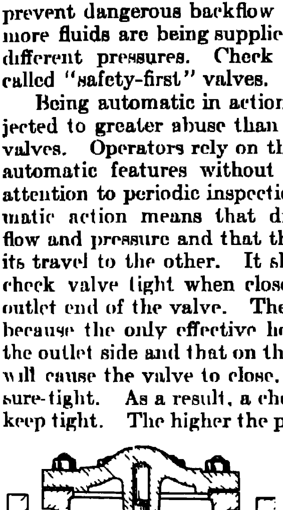

Fig. 11-18. Lift check valve.

Swing Check Valves. In the swing check design, flow through the body is very similar to that of a gate valve. The disc seats against a bridge wall (across the line of flow) and is hinged to a pin placed crosswise of the body above the bridge wall. The disc is free to swing through an arc between the bridge wall and the body or cap and far enough from the bridge wall to permit full flow through the valve when the disc is in wide-open position. The simple explanation is that the disc is held off its seat by flow in one direction and is returned to its seat by reverse flow or gravity (Fig. 11-17). The location of the bridge wall and the relationship in position between the hinge pin and the seat is such that, with no pressure or flow through the valve, the disc is held to its seat by gravity.

Lift Check Valves. The lift check (horizontal or globe type, Fig. 11-18) is designed so that flow through the valve lifts the disc away from its seat, and the force of gravity or back pressure holds the disc to its seat when closed. In this design it is common practice to use bodies similar to the regular globe or angle valves. In lift check valves having a metal disc, the disc is usually renewable and regrindable; in the composition-disc type; the disc is, of course, renewable. To ensure proper seating, the disc must be accurately guided.

FITTINGS

Fittings comprise a considerable part of any piping system and, in addition, constitute a good portion of the aggregate over-all cost. Further, and probably most important, is the fact that pipe itself is usually trouble-free if proper materials for the service have been selected, while joints are likely to be responsible for any unlooked-for maintenance costs which may occur. The working pressure and the nature of the service for which fittings are to be used have an important bearing on their design, and the wide variations in service conditions have necessitated the development of many different types and patterns as well as the use of different metals and alloys.

Groups of Fittings

The seven groups into which fittings (joints) generally fall are as follows:

1. **Screwed Ends.** Screwed ends are used more often owing to the fact that they make a substantially permanent connection—a very satisfactory metal-to-metal joint—are adequate for reasonable pressures and temperatures where piping is used, and, last but not least, are economical to use. It is well to note that they are most popular in the smaller sizes because the larger the pipe, the more difficult it is to make up a screwed joint.

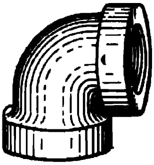

Fig. 11-19. Screwed-end elbow.

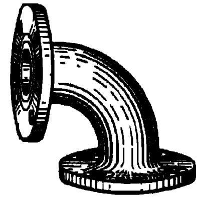

Fig. 11-20. Flanged-end elbow.

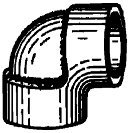

Fig. 11-21. Socket-welding elbow.

2. **Flanged Ends.** Flanged ends are used where conditions make screwed ends impractical and where bolting up the joint is advantageous. Although some flanged ends are made in sizes as small as ½ in., they are most generally used for lines 4 in. and larger because of their easier assembly and takedown. Further, flanged joints are made up with much smaller tools than are required for screwed connections of comparable size.

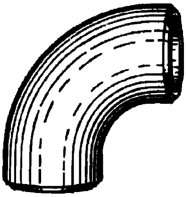

Fig. 11-22. Butt-welding elbow.

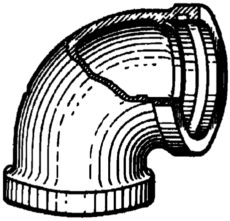

Fig. 11-23. Elbow with ends for brazing.

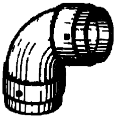

Fig. 11-24. Elbow with solder-joint ends.

3. **Welding Ends.** Welding ends are generally grouped under two headings: "socket-welding," primarily used in connection with small diameter piping; and "butt welding," for general all-around use and for any pressure or temperature to which the piping may be subjected. Also, welding ends are generally used on lines not requiring frequent dismantling.

4. **Brazed Ends.** Brazed ends are made with a brazing ring insert, having end joints similar to a socket weld or solder fitting as described herein. These ends are satisfactory for many installations such as steam and water lines, in process industries, refrigeration, etc. Like the solder end, they are often preferred as a means of obtaining a more permanently tight joint than is possible with a screwed end.

5. **Solder-joint Ends.** Solder-joint ends have been perfected for the purpose of forming a smooth, durable, and pressure-tight union between copper tubing and the

fitting. Fittings of this type are very often used in plumbing and heating lines, lubricating oil lines around machines, for services such as water, air, vacuum, brewery, or distillery liquors, and other nonhazardous and noncorrosive systems.

6. Hub and Spigot Ends. Hub and spigot ends are generally limited to valves and fittings specified for use with gas and water mains, sewage piping, or soil pipe, generally. The joint is assembled on the socket principle, with pipe inserted into hub end to valve or fitting, then caulked with oakum and sealed with molten lead. Hub-end fittings are usually made of cast iron and used with cast-iron pipe having diameters that differ from steel pipe. Variations of this joint for use with wrought-iron or steel pipe are known as the Matheson, Converse, etc., joint.

7. Flared Ends. Flared-end fittings are commonly used for copper and plastic tubing up to 2 in. in diameter. The end of the tubing is flared or skirted and a ring nut is used to make a union-type joint.

Common Types of Fittings

There are many patterns of fittings, each of which is designed for a particular and specific purpose, and the complete assortment is sufficient to care for any known joining problem. Pipe fitters can make up any simple or complex job with a minimum number of fittings and in strict accordance with specifications and codes.

Fittings are made in the same variety of metals as valves (brass, iron, steel, various alloys) and in corresponding pressure classes and end connections and in all standard pipe sizes. All types of fittings, however, are not made in all sizes and materials. Even the regular range of fittings includes a great multiplicity of items, and to show them all here would be practically impossible. An acquaintance with the most common types as illustrated and a general knowledge of the typical variations is advantageous. Generally speaking, these patterns are as follows:

Flanges
Elbows
Tees
Crosses
Reducers
Bushings
Couplings
Nipples
Unions
Return bends
Y bends or laterals
Caps and plugs

INDUSTRIAL PIPE INSULATION

BY R. C. PARLETT

Chief Engineer for Insulation, Johns-Manville Corporation

AND J. F. STONE

Staff Manager, Refrigeration Insulation, Johns-Manville Corporation

HIGH- AND MEDIUM-TEMPERATURE PIPE INSULATION

Proper thermal insulation is required on heated piping and related equipment, principally for the economy effected by the heat or fuel savings and the resultant reduction in production costs. However, it is frequently needed for other important purposes either alone or in conjunction with fuel savings. For example, insulation is used to ensure a minimum temperature drop in liquids and gases conveyed through pipes, ducts, and flues; to keep heat away from areas where it is not wanted in order to produce more efficient or comfortable working conditions; to protect against the hazards of fire or injury to personnel from contact with heated surfaces; to reduce strain on heated equipment by too rapid cooling, as in the case of exposed high-temperature pipe flanges and boiler brick settings; to maintain uniform temperatures in equipment in order to effect a desired chemical reaction; to prevent condensation of gases, *e.g.*, in maintaining the superheat in a steam line supplying a turbine or in flues to prevent corrosion of the metal flue; and for many other purposes.

Uninsulated Heated Surface Losses. Engineers generally recognize that it is good economy to insulate heated pipes, but other surfaces such as flanges and fittings often go unnoticed as they do not realize the magnitude of these losses.

That the area of these surfaces can total to a large quantity is readily seen from Table 11-7 which shows the areas of bare fittings and flanges. A single pair of 6-in. standard flanges has an area of 1.8 sq ft and is equivalent to a linear foot of 6-in. pipe. The loss of heat is not visible as in the case of steam leaks which would quickly be remedied by tightening and packing. The heat losses are nevertheless just as real and continuous.

When the magnitude of these losses is known, the need for a substantial saving of this wasted heat is readily understood. We all have difficulty in visualizing heat units (Btu), but when we talk of their equivalent actual cost in dollars or in pounds of coal, the extent of the losses is readily apparent. Figure 11-26 shows the equivalent losses in dollars per square foot per year (365 days of 24 hr) from bare heated surfaces. This is readily applied to different kinds of fuel of different costs and heating values burned at different efficiencies, as determined from Table 11-8 (see page 750). In considering the cost of heat, the cost delivered at the apparatus should be used. This includes not only the cost of fuel but may also include handling costs, depreciation, and other fixed charges on heat-generating and -transmitting equipment such as boilers, etc. Table 11-9 gives an example of the magnitude of these same losses in equivalent pounds of coal for a given set of operating conditions.

Table 11-9 shows the amount of heat energy lost, and coal consequently wasted, by the dissipation of heat through uninsulated surfaces. The calculations are based upon an available heat value per pound of coal of 10,000 Btu, which is equivalent to a boiler efficiency of 70 per cent using coal with a calorific value of approximately 14,000 Btu per lb. The figures are based also on continuous service, 24 hr per day, 365 days per year, with the average temperature of surrounding air at 70°F. A lesser boiler efficiency or inferior grade of coal would show even greater waste of fuel.

Monetary Value of Insulation. In referring to Fig. 11-26, it will be seen that bare-surface losses increase rapidly with increased temperature of the surface; hence the need for insulation is even more important the higher the temperature. A

Table 11-7. Areas of Flanged Fittings and Equivalent Pipe Lengths

Figures in columns under Area give surface areas in square feet.

Figures in columns under Pipe lengths give the number of feet of pipe which has an area equivalent to the area of the fitting.*

specific example is a boiler drum operating 7,200 hr per year at approximately 150 psi gauge pressure (366°F) with boiler-room air temperature of 75°F, or a temperature difference between boiler and air of 291°F and heat cost of 30 cents per million available Btu. The loss per square foot per year is

$$\$2.46 \times [7,200/(365 \times 24)] = \$2.02$$

Proper type of insulation for this service, saving over 90 per cent of this loss, can be applied at far less than half of 1 year's saving. This shows that insulation is an

Table 11-9. Example of Coal Waste Due to Heat Loss from Uninsulated Surfaces

excellent investment and illustrates the need for insulating such surfaces as boiler heads, flanges, and fittings, which are often left bare even when piping is adequately insulated

Insulation is paid for whether it is bought or not because the cost of the heat loss without insulation in 1 year is generally considerably greater than the insulation cost.

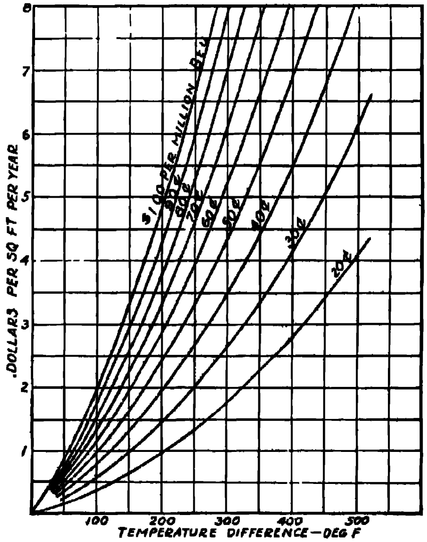

FIG. 11-26. Cost of heat losses per year at various values of heat.

Moreover, this heat-loss cost goes on year after year, so in effect the equivalent cost of insulation is paid out many times.

Theory of Losses from Heated Surfaces. Before discussing savings further, consider the source of the data on bare losses from heated surfaces. The loss from any heated surface exposed to air is made up of two components, one designated "radiation" and the other "convection." The radiation component has been expressed by Langmuir,[1] according to Stefan-Boltzmann in Eq. (1),

$$q_r = 0.174\epsilon[(T_1/100)^4 - (T_2/100)^4] \tag{1}$$

where q_r = rate of heat transfer from surface by radiation, Btu/(hr)/(sq ft)
ϵ = emissivity coefficient
T_1 = absolute temperature of hot surface, deg F
T_2 = absolute temperature of surrounding objects, deg F

showing that the loss is dependent principally upon the difference in the fourth powers of the absolute temperatures of the radiating surface and of the surroundings and also upon the nature of the surface and surroundings, whether "bright," "dull" (in reference to heat rays, not to light rays), etc., and to some small extent upon the geometrical arrangement. It should be understood that the radiation portion of the loss is the only part that is affected by "brightness" of the surface. It has been shown by test that, other than polished metal surfaces, all ordinary materials such as iron and steel, brick, wood, concrete, plaster, as well as nonmetallic paints irrespective of their color, have practically the same radiation loss.

Copper, brass, and aluminum have been shown to have lower radiation loss when new and brightly polished; but these losses increase in service owing to oxidation and by soiling from oil, grease, dust, and dirt. Therefore, it is an unnecessary refinement, not warranted in practice, to differentiate between the types of metal used, particularly as ferrous pipe is by far the most generally used for heated piping. However, it can be shown that, even when applied on new commercially finished copper and brass pipe, insulation pays a satisfactory return on its investment.[2]

The loss by convection, according to Eq. (2) developed by Langmuir,[1] for still air

$$q_c = 0.296(T_1 - T_a)^{5/4} \tag{2}$$

where q_c = rate of heat transfer, from surface by convection, Btu/(hr)/(sq ft)
T_a = absolute temperature of air, deg F

under average conditions, is dependent principally upon the five-fourths power of the difference in the absolute temperatures of the heated surface and the air. It is also known that the shape and the position of the surface with respect to the natural air currents set up by the convection loss have some effect and that curved surfaces of small diameter lose heat at a greater unit rate than large diameters. It should be noted here that the term "still air" is used to denote only the condition where natural air movement due to the heat dissipated from the pipe exists, and no forced or artificial circulation is present. However, the greatest affect on convection is that due to currents such as would be occasioned by forced air circulation indoors or wind blowing on outdoor equipment. Equation (3) (Langmuir's equation[1]) shows that the increase in convection by air circulation is dependent upon the velocity.

$$q_{cv} = q_c \sqrt{(v + 68.9)/68.9} \tag{3}$$

where q_{cv} = rate of heat transfer from surface by convection at any velocity, Btu/(hr)/(sq ft)
v = air velocity, fpm

The total heat transfer from any surface can thus be calculated by adding the radiation loss to the convection loss for the given air velocity.

How Test Data on Bare-surface Losses and Theory Agree. A number of tests have been made on heated surfaces, mainly on pipes, some by accurate electrical measurement of heat loss. These test results are shown in Fig. 11-27 compared with values calculated for combined radiation and convection under still-air conditions using Langmuir's equations (Eqs. (1) and (2).

It will be noted that in Fig. 11-27 there is little variation due to pipe size except for the very small diameters and that the McMillan results are representative of all tests. For this reason all bare-surface losses in still air used in this subsection (Table 11-10) have been based on these test results together with subsequent tests in the McMillan laboratories extending the data to 1000°F.

Test results on surfaces subjected to various air velocities have not been as numerous as still-air tests, probably owing to the larger number of variables which would have to be studied. Tests by Taylor[3] and Fulton and Parlett[4] have shown large increases in heat loss with small increase in air velocity and values even larger than those shown by Langmuir's equation. Langmuir's data have been generally used because of their completeness. Figure 11-28, based on these data, shows how the total loss increases compared with still-air conditions. It shows that, for an air velocity of only 10 mph (less than the average yearly wind velocity in New York City), the loss is 140 to 210 per cent of that under still-air conditions for the temperature range shown. Since Langmuir's figures are conservative, we can readily see the added importance of insulation, as many surfaces in the plant are exposed to circulating air.

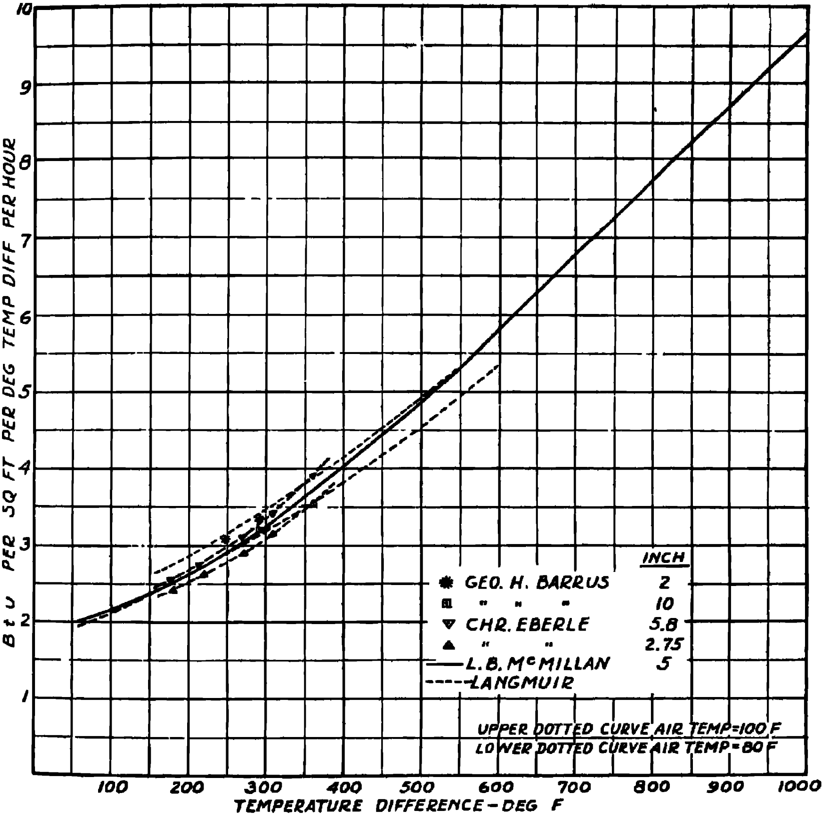

FIG. 11-27. Rate of heat transfer from metal surface to air. (*Barrus, Eberle, McMillan, and Langmuir.*)

Even at a velocity of only a few hundred feet a minute, the increase in loss may be as much as 50 per cent. Most indoor heated surfaces are subject to circulating air a greater portion of the time, and on outdoor apparatus and piping the effect is even greater.

Savings with Insulation. The large savings or reduction in heat losses from bare surfaces that can be made by proper insulation are definitely known from many tests. All standard insulating materials have been tested in some laboratory, and some manufacturers regularly and periodically test their products in their own laboratories to determine insulating value and to ensure uniformity in the product. These tests are run on electrically heated pipes and plates where the heat loss can be measured electrically within an accuracy of 1 per cent.(5, 6)

Pipe and insulation outer surface temperatures are accurately measured with thermocouples; and the tests are made in a closed room under still-air conditions with accurate air-temperature control.

The "conductivity" of an insulation is the *rate* of heat transfer through a homogeneous material in one direction (perpendicular to an area) per unit time per unit area per unit temperature gradient and is expressed as k = Btu/(hr)/(sq ft)/(deg F temperature difference between surfaces per 1 in. thick).

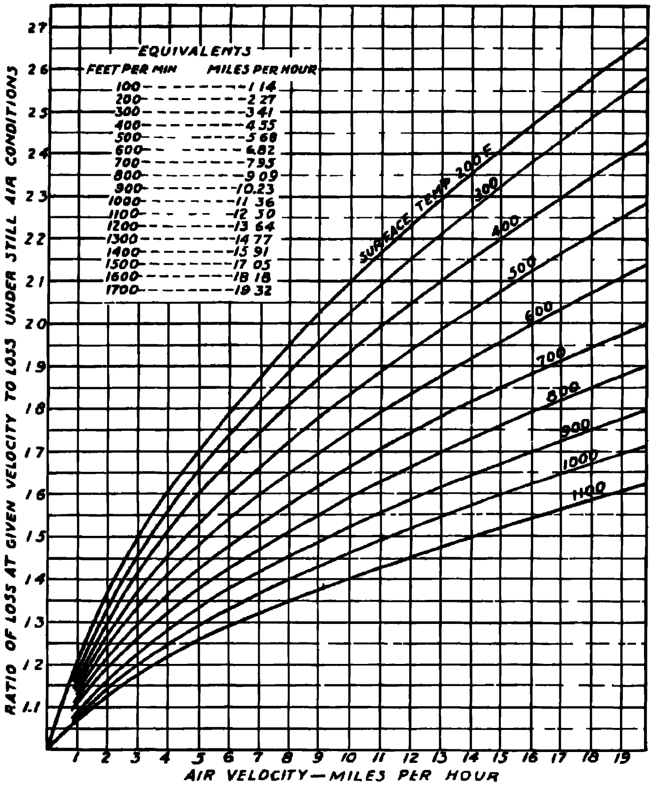

FIG. 11-28. Effect of air velocity on bare surface loss (temperature of air, 80°F).

The conductivity can be calculated from the measured Btu loss from the pipe, using the well-known rational equation for flow of heat, Eq. (4).

$$C_2 = \frac{(t_1 - t_2)}{[r_2 \log_e (r_2/r_1)]/k} \tag{4}$$

where C_2 = rate of heat transfer per sq ft of outer surface of insulation, Btu/(hr)(sq ft)
t_1 = temperature of warmer surface of insulation, deg F
t_2 = temperature of cooler surface of insulation, deg F
r_2 = outer radius of insulation, in.
r_1 = inner radius of insulation, in.
k = conductivity, Btu/(hr)/(sq ft)/(deg F temp diff between surfaces per 1 in. thick)

Table 11-10. Heat Loss from Bare Surfaces

Losses given in Btu per hour per linear foot of bare pipe at various temperature differences (pipe-air). (For finding losses at temperatures between those shown, the Btu increments per degree are given in lightface type between the main columns.)

900	7830.0	17.73	8.700
950	8716.3	18.67	9.175
1000	9650.0		9.650

The conductivity, calculated from such tests can then be applied in the same type of equation [Eq. (5)] to determine the loss on a pipe or other curved surface of different

$$U_2 = (t_1 - t_a) \Big/ \left[\frac{r_2 \log_e (r_2/r_1)}{k} + \frac{1}{h}\right] \qquad (5)$$

where U_2 = over-all rate of heat transfer per sq ft of outer surface of insulation, Btu/(hr)/(sq ft)

t_a = temperature of air on cooler side, deg F
h = rate of heat transfer from outer surface of insulation to air, Btu/(hr)/(sq ft)/deg F

diameter, which makes it unnecessary to test insulation in every pipe size in which it is manufactured in order to determine the losses. The conductivity may also be used in the same type of rational heat-flow Eq. (6) for calculating the heat loss from a flat

$$U = \frac{(t_1 - t_a)}{(L/k) + (1/h)} \tag{6}$$

where U = over-all rate of heat transfer, Btu/(hr)/(sq ft)
L = thickness of insulation, in.

surface where the insulation would be applied in the form of flat blocks.

The heat losses determined in this manner are shown in Table 11-11 for 85% magnesia block, the universal standard insulation for temperatures up to 600°F. Table 11-11 applies only to blocks when used on flat surfaces or curved surfaces of very large diameter and not to pipes. Similar tables of heat losses for all pipe sizes and thicknesses of insulation are furnished by the insulation manufacturers for all types of insulation.

The losses from bare surfaces are also given, and the magnitude of the savings is shown. As an example, take the loss from the boiler drum, previously referred to, which operates at 150 psi (366°F). This is found to be 59.2 Btu/(sq ft)/(hr) when the drum is insulated with 2-in.-thick 85% magnesia. The loss from the same drum bare is 934.8/Btu/(sq ft)/(hr), or over 15 times as large. Hence a saving of 875 Btu/(sq ft)/(hr) is made which is over 14 times as much as the loss from the insulated pipe. The percentage of the bare loss that is saved is 93.6 per cent.

The Btu losses and savings under still-air conditions shown in Table 11-11 can be converted into equivalent pounds of steam or coal or other fuel, or dollars, by direct calculation. In order to determine the equivalent pounds of steam, it is necessary only to divide the Btu by the heat in a pound of steam above feed-water temperature. To convert Btu into equivalent pounds of coal or other fuel, divide by the Btu available per pound of fuel (Btu calorific value of fuel multiplied by heat-plant thermal efficiency). To convert Btu to equivalent dollars, the value of the heat per million available Btu must be known. As previously stated, this figure should be the delivered cost of the heat at the point where it is dissipated and may include not only the cost of fuel and labor of handling it but the fixed charges on the steam or other heat-generating and -transmitting equipment. The heat cost of the fuel alone can be determined directly from Table 11-8 when the thermal efficiency is known.

The magnitude of the losses and savings effected by proper insulation in a plant can be seen by referring again to a simple item such as the two heads with an area of 15 sq ft on a single boiler drum. The boiler operates at 150 psi for 7,200 hr per year, generating steam at a total cost equal to 30 cents per million available Btu, or approximately per 1,000 lb steam. The yearly bare loss from the two boiler drum heads amounts to 100,958 lb steam, or $30.28. The yearly savings when insulated with 2-in. 85% magnesia block are 94,414 lb steam, or $28.32. Other individual items similar to this one will be multiplied many times in some plants. Steam-generating or boiler-room equipment, such as boilers, turbines, pumps, heaters, and piping, is generally conceded to require proper insulation, although it is not always properly insulated. Besides these, there are savings to be effected throughout the plant by the use of proper insulation on such heated equipment as process tanks, heat exchangers, furnaces, waste-heat boilers, etc. Surveys made in each plant to determine the loss on all heated equipment generally show much equipment where the possibilities of savings have never before been explored.

The heat-loss table for 85% magnesia block is based on still-air conditions. It has already been shown that bare losses increase rapidly with increase in air velocity over the surface. For example, 40 to 110 per cent increase with a wind or air velocity of only 10 mph. The effect on well-insulated surfaces, however, is very small by comparison; the maximum increase due to a wind velocity of 30 mph being only about 15 per cent for 1-in.-thick insulation, 10 per cent for 2-in.-thick insulation, and 5 per cent for 3-in.-thick insulation; and at lower velocities there is even less effect. This small increase for well-insulated surfaces is due to the fact that air motion over the surface of the insulation reduces only the resistance to heat flow offered by the film of air at the surface and does not affect the internal resistance to heat flow offered by the insulation proper, which is many times as large as the surface resistance. This is at once apparent if we consider an example using the heat-flow equation for flat materials. Consider a particular case of a $1\frac{1}{2}$-in.-thick insulation, having a conductivity of 0.5 Btu/(hr)/(sq ft)/(deg F temperature difference between surfaces per 1 in thick) and a surface-film coefficient of heat transfer of 2.0 Btu/(hr)/(sq ft)/(deg F temperature difference, insulation surface to air) under still-air conditions. Then

Insulation resistance = thickness/conductivity = 1.5/0.5 = 3.0
Surface resistance = 1/heat-transfer coefficient = 1/2.0 = 0.5
Total resistance = 3.5
Rate of heat transfer = 1/total resistance = 1/3.5 = 0.28 Btu/(hr)/(sq ft)/(deg F temp diff)

If the surface resistance is reduced to such an infinitesimal quantity as to be practically eliminated, as from the effects of wind and rain on an outdoor installation, we find that the rate of heat transfer becomes

1/3.0 = 0.33 Btu/(hr)/(sq ft)/(deg F temp diff)

in which case the maximum possible increase in heat transfer is

$$[(0.33 - 0.28)/0.28] \times 100 \text{ per cent} = 18 \text{ per cent}$$

Thus it is seen that, since air motion increases insulated losses only slightly compared with the increase in bare losses, the saving when air motion is present is much larger than the saving under still-air conditions. Therefore, all analyses of savings based on still-air conditions are extremely conservative.

It should be noted that the example of the effect of air flow in increasing heat losses from insulation, together with the figures given, is based on the assumption that the insulation is tightly sealed. However, if joints are left open or the insulation is cracked to the extent that air can circulate through them, the increases will be far greater than those illustrated. Therefore, insulation should always be applied snugly to the pipe with joints sealed as tightly as possible. On outdoor equipment this is particularly important, in which case weatherproof jackets should also be well lapped and sealed. Any plant-insulation survey should take note of these points since no insulation that contains open joints or cracks or is loosely hanging in place is effecting the maximum savings possible.

Surface Temperatures Not a Reliable Measure of Heat Loss. In making plant surveys to determine surfaces losing heat, it should be stressed that no attempt be made to judge the need by the feel of the surface or even by measuring the surface temperature. Surface temperature alone is absolutely no measure of heat loss. The surface temperature will depend upon the temperature of the surrounding air, the proximity of other hot or cold objects, the velocity of the air adjacent to the surface, and the nature of the surface, whether polished, dull, etc. It is impossible to evaluate all the variables affecting a particular surface-temperature reading and thus to determine from it the actual heat loss. As an example, it is obvious that, with a temperature of 125°F on the side walls of two adjacent boilers a few feet apart and the confined air between at approximately the same temperature, the wall may be losing practically no heat. On the other hand, the rear boiler wall at only 100°F radiating heat to a cold exterior building wall at 50°F a few feet away is losing a relatively large quantity of heat.

Air circulation, which exists in all installations, causes such large variations in heat losses with the same temperature differences that, with an air velocity of only a few hundred feet a minute, the surface temperature becomes meaningless. As previously shown in the resistance example, the effect of air motion over insulation is to lower the surface resistance, or, stated in another way, to increase the rate of heat transfer from the surface. This cools the surface to a lower temperature than it would have under still-air conditions, and hence with a lower surface temperature, more heat is actually being lost than under still-air conditions. It was also shown in the resistance example that the effect of moving air on the over-all heat loss through insulation is small, but we can see from the above example that surface temperatures are not affected in the same proportion for a number of reasons. Hence they are valueless for measuring heat losses.

Insulation Types Available. There are a number of types of insulations available, the more common being described in the following material. The properties of weight, temperature-use range, and typical conductivity values are all shown in Table 11-12. These pipe insulations are, in general, furnished to fit all standard sizes of steel pipe and copper tubing in 3-ft-long cylindrical or semicylindrical sections or curved segments in thicknesses starting at 1 in. and increasing in thickness by $\frac{1}{2}$-in. increments. Some types are also furnished in "standard" thickness ($\frac{7}{8}$ in. for pipe sizes $\frac{1}{2}$ to $1\frac{1}{2}$ in.; $1\frac{1}{32}$ in. for 2 to $3\frac{1}{2}$ in.; $1\frac{1}{8}$ in. for 4 to 6 in.; $1\frac{1}{4}$ in. for 7 to 10 in.; $1\frac{1}{2}$ in. for 12 in. and larger) and "double-standard" thickness (two-layer) ($1\frac{15}{16}$ in. for $\frac{1}{2}$- to $1\frac{1}{2}$-in. pipe sizes; $2\frac{5}{32}$ in. for 2 to 3 in.; $2\frac{1}{4}$ in. for $3\frac{1}{2}$ and 4 in.; $2\frac{5}{16}$ in. for $4\frac{1}{2}$ to 6 in.; $2\frac{1}{2}$ in. for 7 to 10 in.; 3 in. for 12 in. and larger). Pipe insulations are regularly furnished with light canvas pasted on the outer surface. The materials are also furnished in flat or curved blocks of such standard sizes as 3 by 18 in., 6 by 36 in., and 12 by 36 in. in regular thicknesses, increasing by $\frac{1}{2}$-in. increments from 1 in., for application to flat or large-diameter curved surfaces. Cement or dry-powder insulation, to be mixed with water, is furnished for application to small fittings and surfaces too irregular to apply blocks. Both block and sectional-pipe insulation have lower thermal conductivity than cement and hence are to be preferred wherever applicable. Sectional-pipe and curved segmental insulation are wired or metal-banded to the pipe. Blocks are usually wired in place and finished with ½ in. of asbestos cement applied in two coats and reinforced with hexagonal wire mesh. This gives a smooth, hard, continuous surface.

Pipe insulation has been applied to steel pipe or metal flues and ducts on the outer or room side for pipe temperatures reaching from 950 to 1050°F. For higher temperatures, as in cylindrical steel flues carrying waste-heat gases operating up to 1200°F, internal insulation has been used, the lining consisting of hard-surface premolded special diatomaceous-silica blocks. Recent operating tests have been successfully made by the United States Navy using internal insulation on gas-turbine piping where gases were 1450°F. This 3,000-hp plant is the first large gas turbine reported ever to have operated continuously at peak efficiency functioning successfully at such high temperature. The insulation used was calcined diatomaceous silica 1900°F preformed segmental insulation applied in three layers. The insulation is finished on the inside with a high-temperature special alloy-steel liner while the regular carbon-steel outer pipe is kept at a safe temperature by means of the insulation between.

Table 11-12. Thermal Conductivity k of Different Types of Industrial Pipe Insulations for High- and Medium-Temperature Piping

Material	Density, pcf	General usage limit	Mean temperature, deg F							
			100	200	300	400	500	600	700	800
			k,* Btu/(hr)/(sq ft)/(deg F/in.)

Expanded-vermiculite type	17–20	Up to 1000 F	0.81	0.87	0.93	1.00	1.07			

* Average of values from one laboratory on materials of various manufacturers.

85% Magnesia Type. This is the most widely used of the various types for application on hot surfaces up to 600°F. This is a lightweight molded material composed of approximately 85% hydrated basic magnesium carbonate reinforced with asbestos fiber. Furnished in cylindrical half sections or segments 3 ft long for pipes, in thicknesses of "standard" and 1½ in.; 2 in.; 2½ in. in single-layer and "double-standard" (two layers) and 3 in. (double layer); also in flat blocks 3 in., 6 in., 9 in., and 12 in. wide by 18 and 36 in. long and curved blocks approximately 6 in. wide by 36 in. long. Blocks are regularly furnished in thicknesses from 1 to 4 in. by ½-in. increments. They are readily cut with knife or saw for fitting to bent pipe, fittings, and flanges. 85% magnesia is also furnished in powdered-cement form. It is sometimes used as a second layer over molded diatomaceous silica on high-temperature piping to obtain the most economical and thermally efficiency construction.

Asbestos Felt, Laminated Type. This material consists of asbestos felt, approximately 35 to 40 laminations per in. of thickness, cemented together at intervals with heat-resisting adhesive. It is furnished in cylindrical pipe sections 3 ft long split through one side for springing over the pipe in thicknesses of 1 in., 1½ in., 2 in., and 2½ in. single layer and in 2 in., 2½ in., and 3 in. double layer. It is also furnished in sheet or block form up to 36 by 36 in. in thicknesses from ½ to 4 in. This material, like 85% magnesia, is sometimes used as an outer layer over molded diatomaceous silica for high-temperature piping where the extra ruggedness of this type is required. It is recommended for temperatures up to 700°F.

Mineral-wool Type. This material is composed of synthetic mineral fibers made from rock, slag, or glass by melting and blowing with steam or air. The fibers are held between metal fabrics which are wired to each other by tie wires. It is shipped flat in pipe lengths of 2 ft and widths sufficient to encircle the pipe. This flexible type of pipe covering is used mainly where material must be occasionally removed for pipe inspections, etc., as in oil refineries. It is furnished for pipes and flat surfaces in thicknesses from 1 to 4 in. It is generally used for temperatures up to 800°F where removed frequently.

Molded-asbestos Type. This material is composed principally of natural asbestos mineral fiber, usually brown amosite, bonded with a small quantity of heat-resisting adhesive and molded into pipe sections and blocks. It is furnished in the same general forms and sizes as 85% magnesia and in split half sections up to 30-in. pipe size and in single layers up to 5 in. thick. Blocks are made up to 3 ft by 3 ft by 5 in. thick. It is used for temperatures up to 750°F. It is also combined with high-temperature ingredients and furnished for temperatures up to 1200°F either in one layer or integrally combined with an outer layer of 750° material.

Diatomaceous-silica Type. This is a product made of calcined diatomaceous silica combined with magnesium carbonate, bonding clay, and asbestos. It is also molded like 85% magnesia and is furnished in the same general forms and sizes and also in special thicknesses, nominally 1½ in. and 2 in., but actually of proper thickness to fit snugly inside the outer layers of 85% magnesia or laminated-asbestos felt of standard pipe sizes. It is suitable for 1900°F and is used as the inner temperature-reducing layer in combination with 85% magnesia or laminated-asbestos felt.

Expanded-vermiculite Type. This is made of vermiculite (mica) expanded by heat, which is bonded with asbestos fiber and gypsum. It is furnished in the same general form and sizes as 85% magnesia.

Asbestos-blanket Type. This is a mattress-form insulation composed of woven asbestos-cloth covers filled with amosite asbestos fiber, tufted with wire at close intervals and employing sewed-on metal hooks for wiring to heated equipment. It is used for quick accessibility to bolt heads of turbine flanges, pipe fittings, etc., where insulation must conform to irregular surfaces and be readily removable and replaceable. It is made to order for special sizes required usually in thickness of 1½, 2, and 2½ in. single layer and double layer for greater thicknesses. It is used for temperatures up to 850°F depending upon the type of asbestos cloth used.

Insulating Cements. There are several general classes of insulating cements, the first being a bulky fibrous type such as those composed principally of mineral wool, glass wool, or expanded vermiculite combined with some asbestos fiber and bonding clay. These cements are designed for mixing with water and applying in plastic form to irregular contour surfaces where more efficient block materials are not applicable. They readily adhere to metal surfaces and can be applied in thick layers—about one inch. Another type, such as 85% magnesia cement and diatomaceous-silica cement, is of the same composition as these block materials but is furnished in powdered form. These are also used on irregular surfaces, applied in layers about one-half inch thick. A third type, used principally as a finish over other insulations such as block, is composed principally of asbestos fiber and produces a semihard surface. This type is usually applied in two layers, ½ in. total thickness, over the block insulation and sometimes mixed with portland cement to give still harder surfaces. A fourth type, semirefractory, is composed of asbestos fiber and refractory materials and is used in a ½-in. layer for protecting block insulation when applied as a lining in flues.

Factors Governing Selection of Insulation. The proper selection of insulating material for a particular service is an engineering problem and cannot be left to rule-of-thumb methods. It must be determined that the material has

1. Suitable heat-resisting qualities to withstand the maximum working temperature of the equipment. Laboratory and service heat-resistance tests are the proper guides in this respect. It is not possible, although often attempted, to deduce accurately from the chemical composition what will happen to a particular material under temperature.

2. Low thermal conductivity. Conductivity must be known from accurate laboratory tests over the entire temperature range at which the equipment will operate.

It is not sufficient to know the conductivity at only one temperature since conductivity increases with temperature.

3. Sufficient durability and structural strength to assure long life under the particular service conditions and sufficient internal strength to maintain its original shape and particularly its thickness on which its ultimate insulating value depends.

4. Adaptability. Furnished in a form readily applied to the particular surface.

5. Resistance to moisture or to chemical fumes in some particular installations.

6. Proper thickness to effect the most economical heat saving or to accomplish some particular purpose such as preventing excessive temperature drop or condensation in steam lines or to effect comfortable working conditions, etc.

7. Proper method of application to ensure retention of its original strength and insulating value when in place.

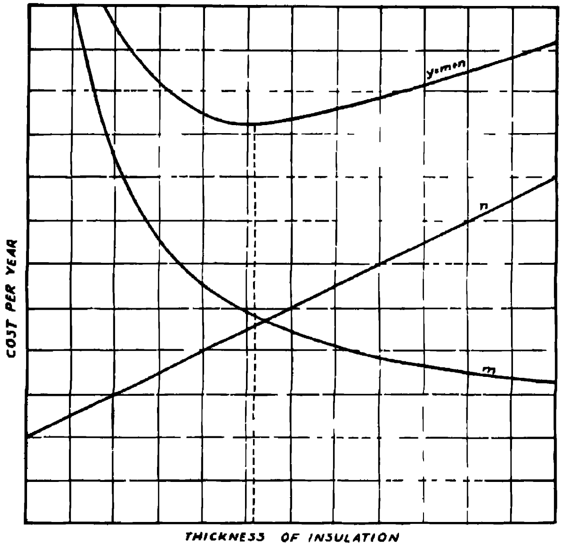

FIG. 11-29a. Economical thickness of insulation.

Since the selection of proper thickness is of primary importance in any installation, both because it affects directly the initial investment and the final heat-saving or other heat-retarding effect, we will consider this in detail.

Selection of Insulation Thickness for Heat Saving. If the principal reason for which insulation is being used is to effect a heat saving, the proper or economic thickness is that thickness the last increment of which pays an adequate return on the investment in that increment.

Figure 11-29a shows that, as the insulation thickness increases, the cost per year n (first cost multiplied by percentage fixed charges) increases and that also with increase in thickness the heat-loss cost per year m decreases. Then the total cost per year y is the sum of the yearly insulation cost and the yearly heat-loss cost or the cost at which a given temperature is maintained. The point on curve y at which the total cost is a minimum is the most economical thickness. Greater thickness would mean that the total cost is too high because of the increased cost of insulation; a lesser thickness, that the total cost is too high because of excessive heat loss due to the insulation's being too thin.

It is possible to determine the economic thickness for any given set of conditions by calculating the yearly cost of heat loss and the yearly cost of insulation for a number of different commercial thicknesses, increasing, for example, by ½-in steps, and then select the thickness which gives the minimum total cost per year. However, this would be laborious if there were a number of such calculations to be made.

To eliminate the necessity for this, McMillan[6] determined rational formulas for the economic thickness applying to both flat surfaces and pipes. He set up equations for the cost per year of heat loss m and cost per year of insulation n and adding the two obtained the equation for the total cost y. Then, to determine the thickness which gave the lowest total cost or the minimum value of y, he calculated this by the mathematical method of differentiating the equation and equating the first derivative to zero. This gave the economic-thickness equation. Since these equations are rather involved mathematically, the results of substituting values in the equations have been plotted in the alignment chart (Fig. 11-29*b*) from which the economic thickness can be accurately determined for all conditions without the necessity of any calculations. To use the chart proceed in the direction shown by the arrows after first determining the following factors:

1. *Hours of Operation per Year.* This should be the actual number of hours the equipment operates.

2. *Value of Heat.* As previously pointed out this should be the total value at the point where the insulation is applied in dollars per million available Btu. Sometimes this value will be higher than the average cost of heat in the plant, owing to the increased production or other useful results produced by the saving of a particular portion of the heat.

3. *Temperature Difference* (heated surface to be insulated minus air temperature). It is assumed that the heated surface temperature stays constant regardless of the thickness of insulation placed on it. This is true for saturated-vapor lines such as steam and can be assumed to be the case for practical purposes for other pipe lines or metal surfaces heated by liquids. Therefore, the temperature difference used in the chart can be the temperature of the vapor or liquid minus the air temperature.

4. *Conductivity of the Insulation.* This is determined from values of the material under consideration, such as shown in Table 11-12, furnished by the insulation manufacturer The actual value of this factor is necessarily dependent on the arithmetic mean temperature of the two surfaces of a material of undetermined thickness. However, since conductivity generally does not change rapidly with small increase in temperature, it will be satisfactory for use with this chart to use the conductivity at the arithmetic mean temperature of the heated surface and the air temperature.

5. *Cost of Insulation.* This is the applied cost which includes material plus labor. The method of determining is explained in detail in the notes on Fig. 11-29*b* and later in the text.

6. *Per Cent Annual Fixed Charges.* This factor includes the return desired on the investment, depreciation, insurance, etc., or the total annual fixed charges applied against the total applied cost of insulation expressed as a percentage.

7. *The Pipe Size.* For which the insulation is required.

In using the chart (Fig. 11-29*b*) start with hours of operation per year and follow through as indicated by the dotted line. The choice of proper economical thickness scale is determined by the choice of heat-value and temperature-difference scales. Example: with scale B heat value and scale A temperature difference, or vice versa, use scale AB economical thickness, etc.

Cost of insulation refers to applied cost. Therefore, to obtain proper discount, first use discount for material alone to determine approximate thickness on which to base material and application costs. Then use the following formula to determine the correct discount:

$$\text{Applied cost in per cent discount from list} = 100[1 - (X + Y)/Z]$$

where X = cost of material; Y = cost of application; Z = list price applying to material.

The thickness is again determined, and if it differs from the first thickness, the procedure is repeated until the thickness does not change.

For pipe insulation, where list prices do not apply, use the following formula to convert from applied cost per linear foot to applied cost per board foot:

$$\text{Applied cost per board foot} = 0.382A/dx$$

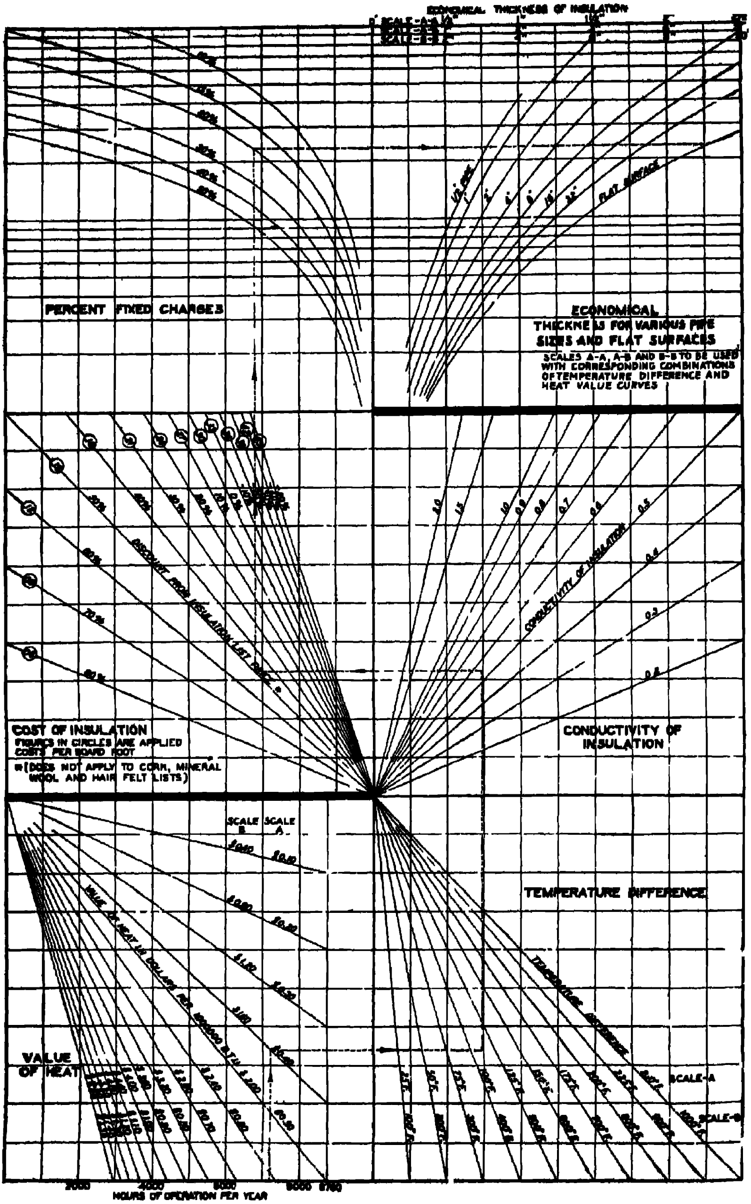

FIG. 11-29*b*. Chart for determining economical thickness of insulation.

where A = applied cost per linear foot; d = outside diameter of insulation in inches; x = thickness of insulation in inches.

Example of Typical Economic Insulation Thicknesses. Typical economic thicknesses determined by means of Fig. 11-29*b* are plotted in Fig. 11-30. This shows how the economic thickness increases with increasing pipe size and with increasing pipe temperature. The particular operating conditions assumed are such as might be found in an average large power or manufacturing plant, *viz.*, heat cost 30 cents per million available Btu, piping kept heated 8,760 hr per year, applied cost of insulation 85 to 135 per cent of list price of insulation, depending upon pipe size, fixed charges 10 per cent, air temperature 75°F. The curves for 800, 1000, and 1200°F pipe temperatures are based on using calcined diatomaceous silica—85% magnesia combination insulation while the curves for 200, 400, and 600°F are based on using 85% magnesia alone. A similar series of curves could be plotted for any other set of conditions existing in a particular plant.

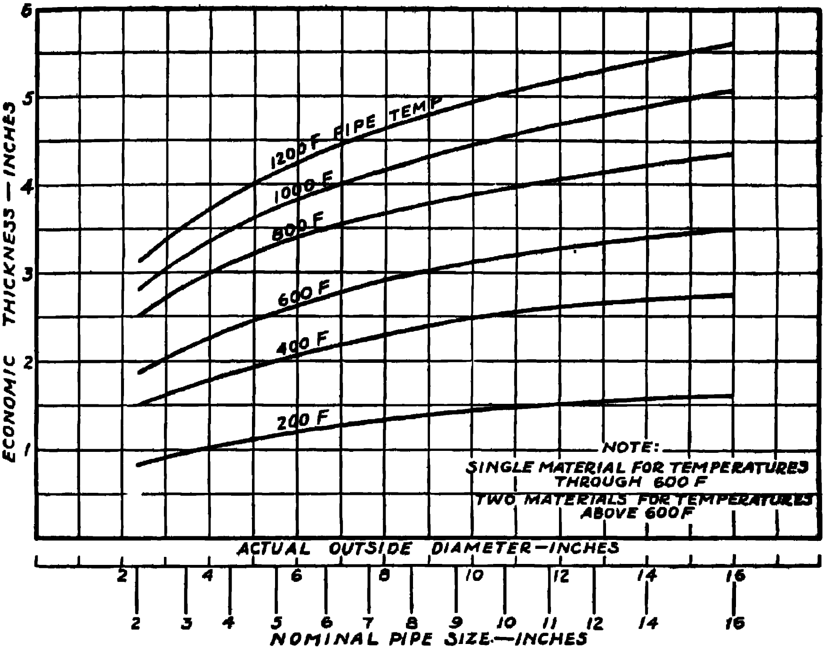

FIG. 11-30. Example of typical economic insulation thickness.

After the total insulation thickness is determined, the nearest commercial thickness, usually nearest ½ in., is selected. Where high-temperature combination insulation is required, a calculation must be made to determine the proportion of the total economic thickness which must be high-temperature material in order to reduce the temperature on the outer-layer material to its safe limit. Here also the nearest commercial thickness must be used and also one which will closely fit a standard pipe size outer layer. Manufacturers furnish special thickness high-temperature inner layers for this purpose.

Where insulation is used for some particular purpose, other than heat saving, such as temperature control, personnel protection, comfort, fire protection, etc., the thickness must be designed to accomplish the particular purpose. For example, if the insulation must limit the temperature drop in a long line carrying superheated steam, it is necessary to calculate the heat loss from the line per hour per pound of steam flowing through the line in the same time and then deduct this loss per pound of steam from the total heat in a pound of steam at the inlet steam conditions to find the total heat in a pound of steam at discharge end of the line. Having previously determined the pressure drop in the line from conventional friction flow formulas, the steam pressure and total heat of the steam at the end of the line are now known, and from the superheated-steam tables the corresponding temperature of the steam for this final pressure and total-heat condition can be found. If the insulation must have a maximum outer surface temperature to protect personnel, a calculation of the temperature gradient through the insulation is made using the resistance conception previously illustrated and the surface temperature determined.

The Importance of Proper Method of Application and Maintenance. The selection of the proper material with full consideration for the temperature and other conditions and the determination of proper thickness are of little importance if the material is applied improperly. For, if it is not properly applied, the actual heat loss may be considerably higher than the calculated value based on laboratory tests. Improper application may cause the insulation to deteriorate, and hence it may not give the years of service for which it was originally planned. It is not possible to give here detailed application specifications for applying insulation to various types of equipment, but there are general factors which apply to the satisfactory application of all insulation. Among these factors are

1. Insulation should be applied securely to and tightly against the pipe or other heated surface. An air space left between the insulation and pipe may result in heat being short-circuited through an open joint or crack. Furthermore, loose insulation is more easily damaged by impact. Some types will sag under vibration if not securely wired or banded in place.
2. Insulation should be applied with joints closely fitted, and multiple-layer insulation should be applied with staggered joints, particularly on high-temperature equipment. Otherwise, pipe expansion and vibration tend to open up through-joints.
3. Insulation should be protected against abuse such as abrasion, knocks, and crushing. Insulation is not a structural material. Hence, where it is liable to be walked upon or have ladders placed against it, runways or scaffold should be provided. This is particularly important on outdoor installations to avoid entry of rain or snow into the material. Where insulation may be subject to impact or abrasion, it should be protected with a suitable sheet-metal jacket or bumper.
4. A moisture-resisting finish should be provided on insulation outdoors, or indoors where it is liable to be splashed from process liquids or otherwise subjected to wetting. This may consist of an asbestos weatherproof jacket over the pipe insulation and asphaltic cement finish over insulation on fittings and irregular surfaces. Weatherproof jackets should be securely wired or banded in place, lapped, and sealed with asphaltic lap cement to prevent deterioration of insulation by wind, rain, and snow. Special provision must be made to protect insulation exposed to strong alkali or acid fumes. Underground pipe insulation requires tile protection specifically designed for the service.
5. All indoor insulation not otherwise protected should be finished with heavy canvas pasted or sewed in place, painted with two coats of lead and oil paint.
6. Sturdily constructed removable and replaceable flange insulation covers should be provided where flanges must be inspected frequently.
7. Last but by no means least important is that insulation should be installed by experienced mechanics.

An insulation properly selected for the conditions often outlasts the useful life of pipe to which it is applied; but in order to ensure its maintaining its initial insulating value throughout its life, it should be periodically inspected and maintained in good condition. This requires attention to such items as prompt replacing of torn weatherproof jackets and canvas finish; replacing of broken wires and sections of insulation; tightening of wires, bands, and loose insulation; repainting of canvas. Any cracks in cement or weatherproof finish should be sealed with the original material since wetting causes loss of insulating efficiency and deterioration of the insulation.

In addition to the foregoing, periodic maintainance inspections should check such items as whether improper pipe insulation is the cause of excessive condensation discharged from traps or whether steam temperatures have been raised beyond the safe limit of the insulating material used. It is also necessary to eliminate water hammer or other causes of excessive vibration which may cause joints to open in the insulation; to stop leaks in steam or hot-water lines as soon as possible since impinging steam causes rapid deterioration, and water from a leak may follow along a pipe, saturate the insulation, destroy its insulating value, and at times cause the insulation to fall from the pipe. Quite often when pipe repairs are made, insulation sections or flange and fitting insulation covers are removed. These should be promptly reapplied as carefully as though it were a new installation since improperly applied insulation is often thermally inefficient and is more liable to failure. Such inspections will pay dividends, not only in heat savings, but in saving of materials and labor.

* Figures are based on an air temperature of −20°F. This is an approximate 60° temperature difference. If air is to be taken at 0°F, the time to cool 10° will be approximately 45 per cent greater. The last column shows minimum amount of water at 42°F to prevent freezing.

These rates of flow include no safety factor to provide for temporary reductions due to lower pressure, etc. Weights of water are per foot, so the minimum flow in a line 100 ft long must be at least 100 times the tabular value.

LOW-TEMPERATURE PIPE INSULATION

The reasons for insulating pipes carrying refrigerants and other low-temperature fluids are similar to those for insulating hot lines. Heat flow is reversible, *i.e.*, a bare pipe 100°F below atmospheric temperature absorbs heat at about the same rate as one 100°F above ambient loses heat.

There are other considerations in addition. Bare, cold pipes drip or become covered with frost and then drip. This promotes corrosion and makes for dirty and unsanitary conditions as well as making space beneath or adjacent to the pipes unsuitable for use. On the economic side it is generally conceded that it costs more to remove heat than it does to supply it; consequently, greater thicknesses of insulation are used on refrigerated lines than on heated ones for equal temperature differences.

In addition to minimizing heat entry into cold piping, there is often the problem of preventing the freezing of water in pipes exposed to winter weather. No insulation, regardless of thickness or low conductivity, will prevent the freezing of still water in pipes exposed to below-freezing temperatures. Insulation retards heat flow; it does not eliminate it. If there is no movement of water in a pipe, it is merely a matter of time until the pipe and its contents reach the same temperature as the surrounding air. Table 11-13 can be used to determine the number of hours to cool water to the freezing point and the minimum flow necessary to prevent freezing in the pipe. It was developed for hair felt but can be used for any blanket-type insulation having a similar conductivity, *i.e.*, 0.30 Btu/(hr)/(sq ft)/(deg F per in.).

Conductivities of hair-felt and mineral-wool blankets are usually stated to be below 0.30. However, an appreciable degree of compression results from the wrapping and securing on a pipe, so a less than nominal thickness or a higher unit heat transfer must be assumed.

Table 11-14 is similar and can be used for any sectional-type pipe insulation made in the conventional three thicknesses and having a conductivity k of approximately 0.30 Btu/(hr)/(sq ft)/(deg F per in.).

Table 11-15 gives rates of heat transfer into cold pipes through sectional insulation of the type just described having a conductivity of approximately 0.30. This table is useful when it is desired to know how much heat will be absorbed by a fluid in traversing a given length of pipe, but it does not allow for the differences in rate of heat transfer into the fluid due to film effect on the inside of the pipe. It is assumed the fluid flow will be fast enough to produce turbulence which minimizes film resistance and that all the heat which can traverse the insulation will be absorbed by the fluid in the pipe.

Effective insulating of pipes to prevent sweating or frosting is based on using a thickness of insulation that will keep the outer surface of the insulation at a temperature above the dew point of the surrounding air. This cannot be done for all conditions. As the air nears saturation, the dew-point temperature approaches the dry-bulb or ordinary thermometer reading, the two becoming equal at complete saturation, sometimes called 100 per cent relative humidity. To prevent condensation under such a condition would require an infinite thickness of insulation. Figures 11-31, 11-32, and 11-33 illustrate this. To use these charts, find out what the climatic conditions are likely to be, and then from a psychrometric chart or table find the dew-point depression or difference between the air temperature (dry bulb) and the dew point. Start from that figure in the column at the left edge of chart, and draw a line horizontally until it intersects the curve representing the over-all temperature difference expected. From the intersection drop vertically to the bottom of the chart, and read the insulation thickness required. If the climatic data are not thought to be very accurate, the column of relative humidities at the right will be accurate enough for most cases. Choose the highest that is likely to obtain for any considerable period, and intersect the over-all temperature difference curve as before. It may be noted that it is rarely worth while to design against humidities over 85 per cent, as there are few areas where higher humidities last for any length of time, and the thicknesses required are unduly expensive.

There are only two types of pipe insulation generally used for low temperatures. One consists of flexible blankets which are wrapped around the pipe, tied on, and a

sealing membrane applied to exclude moisture. On this type, hair felt has by far the longest history. Certain mineral-wool blankets are also offered for the same purpose. Blanket-type insulation has the advantage of versatility. Given enough material on the job, any size of pipe and any combination of fittings may be covered. It has the disadvantage of requiring exceptionally good and careful workmanship, particularly in applying the sealing membrane which protects it. No insulation job can be better than the workmanship of the applicator, but there is more inherent difficulty in sealing over a relatively soft and yielding surface. Also, the chance of the seal being broken by a blow or rough treatment is greater. This type of insulation is the only one that can be employed on hangers that are affixed directly to the pipe.

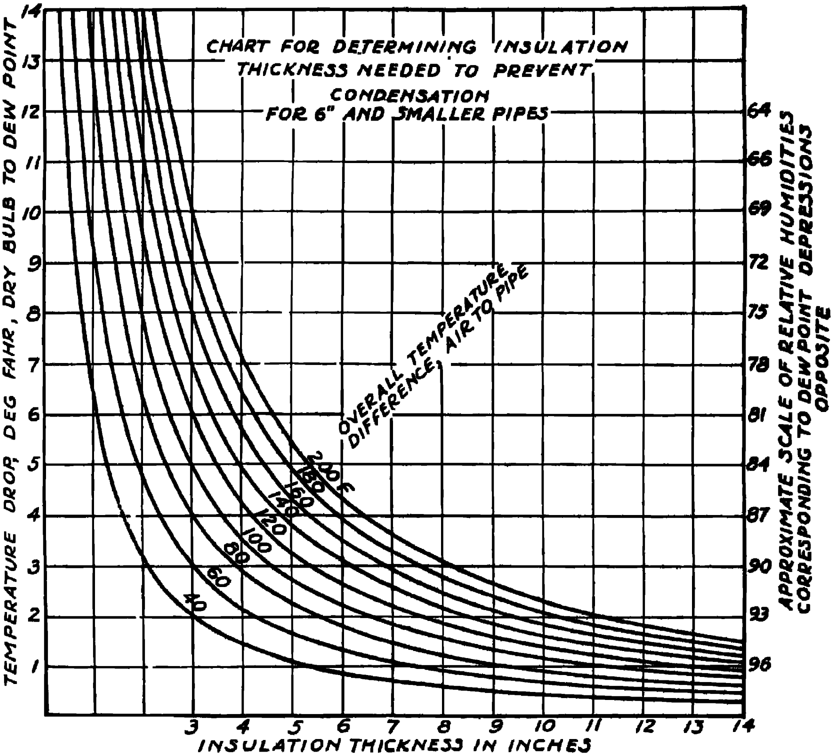

Fig. 11-31.

The second major type of pipe insulation consists of molded or formed sectional overing. Comparatively solid, it is furnished in either half sections 36 in. long or in half sections joined by an outer wrapper providing both a seal and a hinge joining the half sections. Fittings are insulated either with molded jackets or by use of a wrap-on-type insulation as in the type previously described. The sectional-type insulation is easier and quicker to apply. It is also decidedly easier to seal effectively against moisture.

Sealing of low-temperature insulation is of major importance as there is always a pressure, resulting from temperature differences, tending to force water vapor into the insulation, where it will condense. If the temperature is low enough, freezing follows, not only seriously impairing the insulating efficiency but frequently destroying the insulation and corroding the pipe.

Table 11-15. Rates of Heat Transmission Sectional Insulation

The rates of heat transmission given below are expressed in Btu per square foot (and also per linear foot), per hour, per degree temperature difference between fluid in the pipe and air surrounding the pipe. In the case of screwed fittings, where the proportion of fittings to pipe is not unusually high, no great error will be introduced by figuring small fittings, such as ells and tees, as 1 linear ft of pipe; and larger fittings, valves, crosses, etc., as 1½ lin ft. Refer to Table 11-7, Areas of Flanged Fittings, which appears on page 749.

Brine thickness		
Up to 6-in pipe—screwed fittings	9	7
Larger than 6-in pipe—screwed fittings	15	9
All pipe sizes—flanged fittings	16	10
Heavy brine thickness		
Up to 3-in pipe—screwed fittings	11	9
Larger than 3-in pipe—screwed fittings	19	13
All pipe sizes—flanged fittings	20	14

Hanger Details for Pipe Insulation. Steel saddles or shields on the outside of the insulation must be provided in all cases where the pipe hanger or support is not affixed to the pipe (see Fig 11-34)

In most cases, the saddle and outside strap hanger is preferable to fastening the strap or rod support to the pipe, as it does not involve the insulating and the sealing off of a through-metal connection between the cold pipe and warm air

Where extra-heavy loads, difficult to calculate, may throw excessive weight on one or several hangers, it may be advisable to attach supports directly to the pipe as shown in Fig. 11-35. An example of such a condition might be a horizontal line with several risers or branches near together and, possibly, the inclusion of a cluster of valves, etc., within a short length.

The third type of support, the trapeze style shown in Fig. 11-36, is not desirable because of the poor distribution of load on the pipe insulation.

Size of Shields or Saddles. Length = outside diameter of insulation; circumference = approximately 270 deg or ¾ of a circle; gauge of metal = 12 gauge where outside diameter of insulation is less than 8 in. and 10 gauge where outside diameter of insulation is 8 in. or greater.

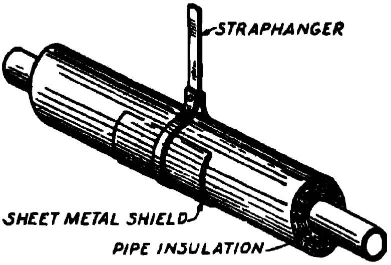

FIG. 11-34. Outside hanger and shield.

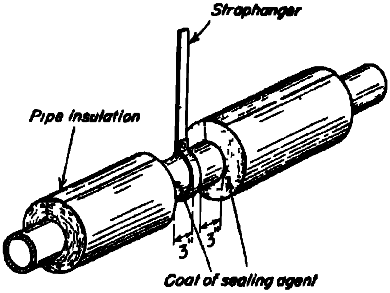

FIG. 11-35. Inside hanger.

Spacing of Hangers. Based on use of ¾ round metal shields and on consideration of structural properties of high-pressure pipe as well as indentation of insulation Where low-pressure pipe is involved, hanger spacing may need to be reduced Table 11-17 is based on straphangers as shown in Fig 11-34: Where unusual hanger loads are involved, the loads per shield should not be exceeded (see Table 11-18)

Table 11-17. Hanger Spacing Based on Pipe Size

Insulation thickness*	Pipe sizes and maximum hanger spacing, ft				
	1½ in.	2½ in	4 in	6 in †	8 in.†
Ice water or light duty	13	17	25	26	34
Brine or standard duty	12	16	23	24	32
Special brine or heavy duty	11	14	22	23	28

* Ice water or light duty, 1.5 to 2 in.; brine or standard duty, 1 8 to 3.2 in ; special brine or heavy duty, 2.8 to 4 0 in.

† Reduce spacing one-third for trapeze-type hangers.

Table 11-18. Loads per Shield

Insulation thickness	Pipe sizes and loads, lb				
	1½ in.	2½ in.	4 in.	6 in	8 in.
Ice water or light duty ..	500	600	900	1,000	1,500
Brine or standard duty.	600	800	1,000	1,100	1,600
Special brine or heavy duty	800	1,000	1,100	1,200	1,800

Sealing and Insulation. Sealing on hanger should be carefully done to keep moisture from running down into insulation. The following steps summarize operations shown in Figs. 11-35 and 11-37: (1) Insulation should be applied not closer than 2 to

3 in. from the hanger on either side. (2) The exposed ends of the pipe insulation should be coated with the sealing agent and the pipe and hanger with protective paint. (3) Two or three (3 for heavy brine) built-up layers of hair felt or equal should be applied with a double wrap of tape per layer sealed to insulation and hanger as shown, and sealing agent should be applied to each layer and all ends. (4) A supplementary built-up layer of hair felt about $1\frac{1}{2}$ in. thick should be carried up the hanger at least 12 in. (5) A double wrap of tape should be sealed to the hanger at the upper end and to the membrane over the insulation at the lower end.

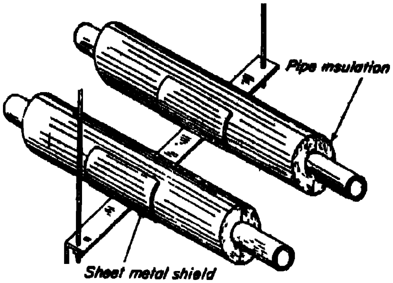

Fig. 11-36. Trapeze hanger and shields.

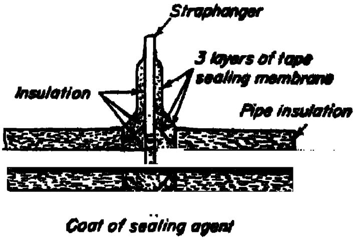

Fig. 11-37. Insulation and sealing of inside hanger.

Mathematical calculations for heat entry into refrigerated pipes and vessels are made in accordance with the same equations detailed for heat losses. There is not, however, a suitable equation for economic thickness of sectional-cold pipe insulation since the list prices of the commonly used materials do not follow any regular law.

RUBBER-LINED PIPE AND PROCESS EQUIPMENT

BY O. S. TRUE

Manager, Tank Lining & Roll Covering Sales,
United States Rubber Company

Rubber-lined pipe, storage, and process equipment is particularly valuable to industry as it incorporates the corrosion and abrasion resistance of the rubber with the structural properties of steel. Furthermore, as the requirements of the process with regard to installation and cure both in the factory and in the field are very flexible and as the limits with regard to size and detail of design are very broad, practically all types of industrial equipment are suitable for rubber lining or covering. In the combination, the rubber provides the necessary corrosion and abrasion resistance, and the steel provides the structural strength, whether the requirement be pressure, vacuum, or mechanical.

NATURAL-RUBBER AND GR-S LININGS

Chemical Resistance. With few exceptions, rubber linings are suitable for use with most industrial solutions. While it is not possible in a brief review of the subject to enumerate all possible materials, a statement of general classifications will suffice to give a reasonable general knowledge of possible applications. In any event, in the absence of specific experience it is best to refer detailed service conditions to the rubber manufacturer for his recommendation.

Rubber linings are suitable for use with the following:

1. Most inorganic acids, including hydrochloric, phosphoric, dilute sulfuric, hydrofluosilicic, etc.
2. Many organic acids, such as acetic acid, tannic acid, gallic acid, etc.
3. Inorganic salt solutions, such as ferric chloride, zinc chloride, tin chloride, sodium cyanide, ferrous sulfate, etc.
4. Inorganic bases, such as sodium hydroxide, calcium hydroxide, etc.
5. Plating solutions, with the exception of chromium, including nickel, brass, tin, zinc, silver, cadmium, etc.
6. Bleach solutions, sodium hypochlorite and chlorine solutions

Rubber linings are not suitable for use with the following:

1. Strong oxidizing agents, such as nitric acid, chromic acid, sulfuric acid above 50 per cent concentrations
2. Aromatic hydrocarbons, such as benzol, toluol, etc.
3. Aliphatic hydrocarbons, such as gasoline, petroleum, derivatives, etc.
4. Chlorinated hydrocarbons

Temperature Resistance. Under most conditions unprotected rubber linings are suitable for temperatures up to 180°F. With protective inner linings of wood or brick higher temperatures are possible. It is rather difficult to define the extreme upper temperature limits as in many cases the combined effect of corrosive solution and temperature must be considered. Under particularly severe conditions the maximum allowable temperature might be 130 to 140°F. Under other conditions 200 to 210°F might be permissible. Here again, in the absence of specific experience, the detailed service conditions should be referred to the rubber manufacturer for his recommendations.

Physical Properties of Rubber Linings. Rubber linings are supplied in a wide variety of compounds varying in hardness from soft rubber to ebonite and in type and degree of compounding as service conditions may require. Semihard and hard linings are usually installed with soft-rubber cushion next to the metal to compensate for differential expansion and contraction between rubber and metal. The usual thickness of rubber lining for pipe and fittings up to 5 in. nominal size, inclusive, is ⅛ in., and for piping of 6 in. nominal size and over and for tanks and process equipment $\frac{3}{16}$ in. For severe services thicker linings are used. In addition to corrosion, abrasion, and temperature resistance, the principal requirement of a satisfactory lining compound is low water absorption. This latter requirement is very important if penetration through the lining to the metal is to be avoided and if permanent protection of the metal is to be provided.

Tensile strength and elongation, which are properties commonly considered in making comparisons of rubber stocks, are not in themselves of particular importance when considering the relative suitability of lining materials. It is possible that a compound with relatively low initial tensile strength and elongation may be more suitable than a compound with relatively high initial tensile strength and elongation. Relative percentage loss of tensile strength and elongation upon exposure to corrosive solutions and temperature is important in that it is an indication of relative rate of deterioration in service, and good aging properties are essential. All the above factors are taken into consideration when the rubber manufacturer makes stock recommendations for any particular service.

Abrasion Resistance. Rubber linings can be compounded to provide remarkable abrasion resistance, with the result that they find wide application in the handling of abrasive slurries and in the hydraulic or pneumatic transportation of various abrasive materials. Such installations may involve abrasion only or a combination of abrasion and corrosion.

Dielectric Properties. Rubber linings are nonconductive and hence are extensively used in electrochemical processes such as electroplating where absence of current loss is essential to economy and quality. The usual test procedure is to ground the metal and expose the rubber surface to a potential of 15,000 volts. This potential will expose defects in material and workmanship but will be repelled by a lining of proper quality.

Other Properties. Rubber lining also has the virtue of noncontamination of product. In other words, a product in contact with rubber does not extract from the rubber materials that will discolor or otherwise contaminate. Rubber linings are frequently used primarily to prevent metallic contamination of product during process, storage, and transportation.

SPECIAL SYNTHETIC LININGS

There are certain synthetic elastomers such as neoprene, perbunan, hycar, etc., which will handle service conditions for which natural rubber and GR-S are not suitable. These materials are resistant to petroleum and its derivatives and have superior resistance to certain other hydrocarbons and chlorinated hydrocarbons. They lend themselves to installation in most types of equipment. Rubber manufacturers will be in position to make proper recommendations with regard to the use of these materials.

METAL PARTS

Metal parts of proper quality and finish are essential to first-quality rubber lining. Plate thicknesses and reinforcements should be adequate to prevent damage to rubber linings due to excessive distortion. Flange thicknesses should be such as to prevent distortion during assembly. Plates should be free from pitting and castings from porosity. Full welding is required at all points to be rubber-covered, and welds must be chipped and ground smooth and be free from porosity. More detailed specifications follow. These specifications are typical of the general requirements in the industry and will be readily met by any competent fabricator familiar with preparation of metal parts for rubber lining.

Metal Specifications for Welded-steel Tanks or Other Welded Parts. *Material.* Material shall be new full-weight American steel, free from laminations or other physical imperfections. All plates shall be flat, with no appreciable buckle or warpage. All sharp edges of sheared plates must be removed, especially on the inside of tanks. The thickness gauge and weight per square foot shall be no less than the figures listed in Table 11-19.

Dimensions. All dimensions shall be detailed on drawing. Unless otherwise specified, the dimensions for steel tanks are to be considered inside dimensions. A tolerance of plus or minus 1/8 in. is permissible on lengths, width, or height on dimensions 24 in. or less, unless otherwise specified. On dimensions over 24 in., a tolerance of plus or minus 1/4 in. is permissible. The same tolerance applies to over-all dimensions when parts are made up in sections.

Table 11-19

Plate thickness, in.	*Weight per sq ft, lb*
7/64	4 375
9/64	5 625
3/16	7 50
1/4	10 2
5/16	12 5
3/8	15 0
1/2	20 0

Construction. 1. Tanks or welded parts shall be fabricated in accordance with standardized commercial practice to obtain a practical product and uniform quality.

2. All tanks shall be constructed with a minimum number of pieces. Rectangular tanks of the open-top type shall be properly reinforced in accordance with accepted practice in order to provide adequate structural strength and to prevent bulging.

3. The companion angles of sectional tanks which are bolted together must be square, plumb, and smooth, and sections must fit exactly when bolted together. The open ends of sectional tanks shall be provided with suitable bracing so they will not become distorted in transit. Sectional tanks shall be permanently match-marked on spots that are not to be rubber-covered accurately to indicate their position when assembled. Parts must be lined up properly when correctly assembled and marked.

4. Fabricator shall supply necessary bolts, nuts, and washers to complete any assembly shown on the drawings as such.

5. On tanks with dished heads, the dished heads are to be flanged in such a manner as to eliminate wrinkles at the knuckle radius.

Welding. 1. All joints over which rubber is to be applied must be continuous solid welded.

2. All welds must be smooth with no porosity, holes, high spots, lumps, or pockets. Peening is required to eliminate porosity, and grinding is necessary to remove sharp edges and high spots.

3. All corners are to be ground to a minimum radius of 1/8 in.

4. Partitions, braces, supports, or other attachments on the inside of the tank must be fitted flush against the adjacent surface and full-welded from all sides. Spot welding is not permissible. (Welds are to be ground per 3 above.)

5. All body seams must be butt-welded, with continuous solid welding throughout, unless tap weld is necessary to meet special requirements.

6. Vendor shall assume all responsibility for strength of welds.

7. Misalignment of plates and butt-weld seams not to exceed 25 per cent of plate thickness and in no case to exceed 1/8 in.

Outlets. The size, construction, and location of outlets shall be in accordance with the instructions on the drawing. All flanges must be parallel with the tank, or in other words, be so applied that the pipe line will leave the tank at right angles to the surface of the tank, unless otherwise ordered. For all closed vessels, suitable for rubber lining, all manholes shall be not less than 18 in inside diameter. Orifices to be ground to a minimum radius of 1/4 in.

Domes and Fittings. When cast-iron or steel domes and fittings are specified, they shall be free from porosity and sand holes.

Tests. 1. Either test or working pressure, or both, of closed tanks will be specified on the specification print. If no pressure requirements are specified, all closed cylindrical storage tanks shall be thoroughly tested for leaks at 5 lb hydrostatic pressure

2. Vacuum tanks must be tested to the vacuum shown on the drawing.

3. If required, the vendor will furnish affidavit of tests.

Metal Specifications for Pipe and Fittings. *Standard Pipe—Screwed-on Flanges.* 1. Pipe shall be standard weight and grade of steel pipe. Pipe below $3\frac{1}{2}$-in. nominal diameter may be butt-welded, all other pipe shall be lap-welded and free from deep seams, ridges, or other imperfections on rubber-covered surfaces. The heavier standard weight for sizes 10 in. and above shall be furnished unless otherwise stated.

2. Briggs Standard pipe thread shall be used, and lengths shall be fitted with ASME 125-lb Standard CI flanges, unless otherwise stated.

3. Flanges shall be made up to a perfectly tight truly aligned fit by machine. No lubricant or oil shall be used or left on thread in making the assembly, but a rubber cement approved by the purchaser may be used. Pipe must be finished flush with face of flange after assembly (see 4 under Alignment, Tolerances, Finishing below).

Fabricated Steel Pipe—Welded-on Flanges. 1. Fabricated pipe shall be of a good weldable quality steel, free from laminations and other harmful ingredients or defects including those of 1 under Metal Specifications on page 777.

2. Flanges on welded sections shall be ASME 150-lb Standard steel slip-on flanges with plain faces unless otherwise specified.

3. Flanges shall be fillet-welded by shielded-arc process in accordance with dimensions set forth in American Tentative Standards for Pressure Piping, except that fillet on end of pipe shall be built up to allow for finishing to a clean metal surface in accordance with 4 under Alignment, Tolerances, Finishing.

4. Butt welds of single-butt type may be used on butted sections. All welds on surfaces to be rubber-covered must be ground down to a smooth metal surface, using a No. 24 grain grade Q wheel or finer and shall be free from pits or other imperfections.

5. All nozzles in headers and other fabricated branch connections shall be extruded where possible. Vendor shall notify the purchaser when extrusion is impossible. Notification in writing of the limitations of this process as to sizes, dimension, etc., shall be considered as notification that other fabrication methods will be used for all units not included within these limitations.

Alignment, Tolerances, Finishing. 1. A tolerance of $\frac{1}{64}$ in. in alignment of all flanges shall be allowed.

2. Boltholes on flanges on each end shall line up with each other within $\frac{1}{8}$ in. (the standard clearance between bolt and drilled flange holes).

3. Tolerance from face to face or center to face shall be $+0-\frac{1}{8}$ in.

4. The inside edge of pipe shall be turned to a radius of $\frac{1}{4}$ in. by tool or grinding wheel 24-grain grade Q or finer. In case where rubber covering is to go over and around pipe end, the end of pipe shall be turned to half circle or approximation of a half circle.

5. Pipe shall be washed free of all oil, grease, or other viscous coating.

Fittings. 1. Flanged fittings unless otherwise specified shall be ASME Standard, 125-lb CI.

2. Fittings shall be free of oil, grease, or other viscous coating and excessive rust.

3. Fittings shall be smooth, nonporous, and free from high or ragged projections as well as large, deep, or irregular pits.

4. Alignment of boltholes shall be as in 2 under Alignment, Tolerances, Finishing, except that, when offset boltholes are specified, tolerance shall be from offset as given on print.

5. Inside edge of fittings shall be finished as set forth in 4 under Alignment, Tolerances, Finishing.

General Standards. These specifications cover details pertinent only to rubber lining. Such details as are standard commercial practice have been omitted. The vendor shall be governed by latest modification of ASME and API concerning such details. Departure from such details shall be made only upon written permission of purchaser.

SCOPE OF THE RUBBER-LINING PROCESS

The rubber-lining process is sufficiently flexible to permit application to a wide variety of equipment under a wide variety of circumstances. If equipment is suitable for rail transportation, the usual procedure is to ship the metal parts to the rubber factory. Size is the controlling factor, and as a general statement, the limitation is 11 ft extreme width by 11 ft extreme height, although in certain cases it is possible to exceed these limitations. In case of doubt, definite clearance limitations should be obtained from the railroad.

If equipment is too large for shipment or if it can be more advantageously installed prior to rubber lining, materials and operators can be sent to the job site and the rubber lining installed in the field. In such cases, the purchaser has to defray the traveling and living expenses of the operators and has to provide at his own expense certain services and facilities which are given in detail below:

Common Labor. Purchaser shall provide such common labor as may be necessary for unloading, storage, and handling of materials, etc.

Storage of Materials. Purchaser shall provide suitable storage space for all materials required for the lining operations. This storage space should be provided as close as possible to equipment which is to be rubber-lined. Temperature of storage space should be maintained at 65°F minimum in order to ensure proper workability of materials.

Workroom and Cutting Table. Purchaser shall provide suitable workroom equipped with proper light, heat, and ventilation and a cutting table for handling of stock, which should be approximately 4 ft wide by 34 in. high by 20 ft long. (For special stocks it is sometimes necessary to have pipe coils installed under the worktable to maintain a temperature on the top of the table of approximately 125°F.) The workroom shall be located as close as possible to the equipment to be rubber-lined. The workroom temperature shall be maintained at 65°F minimum. Room for storage of materials and workroom shall be combined if possible in order to facilitate handling of materials.

Protection of Tanks. If equipment to be rubber-lined is located out of doors in certain latitudes and seasons, it will be necessary to protect the equipment from the weather and to provide heat necessary to maintain a minimum temperature of 65°F. In any event, the equipment must be properly protected against rain and in warm weather from direct exposure to the sun. A satisfactory installation cannot be made if conditions are such as to induce condensation on surfaces prior to cementing and lining. Neither can lining be properly cured unless equipment is protected against excessive heat loss during cure. Reasonable comfort conditions are necessary to ensure proper efficiency of operators and proper quality of the work. The purchaser shall provide such protection and heat as may be necessary depending upon local conditions.

Ladders and Staging. Purchaser shall provide ladders and suitable staging which are to be erected to conform to proper working and safety requirements. Purchaser is also to supply such common labor as may be necessary for dismantling and removal of staging, etc.

Sandblasting. Purchaser shall provide for sandblasting of all surfaces to be rubber-lined to remove all scale, rust, grease, etc., prior to rubber-lining. Sandblasting should be done immediately prior to the start of rubber-lining work.

Ventilating Equipment. Purchaser shall provide a suitable suction blower with nonsparking motor and necessary exhaust duct to discharge solvent fumes a safe distance from the tank.

Electrical Connections. Purchaser shall provide necessary electrical outlets adjacent to equipment to be lined and necessary electricity for lights, ventilating equipment, and testing apparatus.

Steam for Vulcanization. Purchaser shall provide necessary steam for vulcanization and necessary piping for same.

Compressed Air. Purchaser shall provide compressed air with necessary piping if required.

Steel-tank Specifications. Steel tank or other equipment furnished by purchaser for lining shall conform to standard specifications of design and finish required for proper installation of rubber lining.

Safety Regulations. Purchaser shall be responsible that all safety precautions consistent with best safety practice are maintained. The equipment to be rubber-lined must be kept clear of any fire hazards such as sparking motors, open flames, etc. No welding or burning operations are to be permitted in the area adjacent to the job during the installation of the rubber lining. Proper precaution must be taken to prevent any hazardous operation within the area adjacent to the job site. Manholes for access to closed tanks must have an inside diameter of 18 in. In some tanks it is also necessary to provide extra openings for installation of ventilating equipment.

Brick Linings. Rubber-lined equipment is also adaptable to the installation of inner brick linings of acidproof brick and cement to handle conditions involving excessive temperature or exposure to mechanical abuse. Brick linings are installed in the field subsequent to erection or installation of rubber-lined equipment. Thickness and specification will vary with the service requirements.

REPAIRS

Of considerable importance to the extensive use of rubber linings is the fact that repairs may be readily made. Minor repairs are usually made by regular maintenance personnel. Extensive repairs are best handled by experienced operators furnished by the rubber manufacturer. Repair materials of reasonable stability are available and may be stored for considerable periods if protected from extremes of temperature and will keep indefinitely if refrigeration is available.

The repair procedure is essentially as follows:

Surface Preparation. If metal is not exposed or damaged, the surface of existing rubber lining should be buffed so as to expose a fresh rubber surface over the entire area to be patched. If the metal is exposed or damaged or if the existing lining is blistered, the damaged rubber in the area to be repaired must be removed. Enough rubber should be removed to be certain that the lining remaining is securely bonded to the metal. The metal must be thoroughly cleaned and roughened, and the existing rubber lining should be beveled and roughened back for a distance of about three inches around the exposed metal. Sandpaper, power buffer, wire brush, file, etc., should be used as necessary. If a repair is necessary where the metal has been eaten through, the rubber must be cut back sufficiently to allow welding of a repair in the metal. If the welding is carefully done and the area not heated too much, it is usually necessary to cut the rubber back about six inches from the weld. After this has been accomplished, it will then be necessary to cut back the rubber all around the repaired area until a good bond is reached. Adjacent rubber surfaces should be buffed so as to expose a fresh rubber surface for a distance of 2 in. back from the exposed metal.

Cementing. Cements should be applied to the surfaces to be patched by brushing on evenly, allowing sufficient time between coats to allow complete drying. Drying time may be accelerated by exposing surfaces to a jet of compressed air. From three to four coats of cement will be necessary, depending upon manufacturer's specification and instruction.

Freshening. The cemented surface should be freshened lightly with high-test gasoline. The freshened surfaces should be allowed to dry until tacky, but not wet or slippery.

Application of Rubber Stock. 1. The edges of the stock should be skived to obtain correct construction of the finished job. The type of skiving will, of course, depend on whether the sheet is adjacent to a corner, has an overlapping adjacent sheet, or is a small repair to an existing lining.

2. The rubber should be rolled and stitched carefully to remove all air and to obtain contact with the cement throughout, working from the center of the sheet outward to the edges.

3. After the lining has been completely installed, or patches rolled in place, it should be looked over carefully for separated seams, "pulls," etc.

Cure. Exhaust steam should be introduced with perforated pipes, jets, etc., as necessary to get contact with all surfaces If only a small repair is being cured, the steam can be confined to the repaired area by means of a tarpaulin, box, or other enclosure. At least 24 hr in exhaust steam will be required to cure the lining, and more time may be necessary in a large tank or if the heat losses are large.

The above outlines the general repair procedure. Detail will vary with materials and instructions of various manufacturers.

COMMON TYPES OF RUBBER-LINED EQUIPMENT

Storage Tanks (Fig. 11-38). Rubber-lined storage tanks of all types are in general industrial use. The most usual types are the horizontal cylindrical closed type and the vertical cylindrical type, either open top or with cover. Horizontal cylindrical tanks may be provided with dished heads or flat heads and will be suitable for pressure or gravity discharge, depending upon detail of construction. Access is provided through a manhole (18 in. minimum), and flanged openings for various piping connections are provided as necessary. The usual capacities vary from 2,000 to 50,000 gal, although size is not a limiting factor.

This type of tank has many advantages. It is applicable to pressure discharge; it is totally enclosed, thereby affording complete protection from mechanical damage to the rubber lining. It is easy to transport and to install. It is easy to support, and all exterior surfaces are readily accessible for inspection and maintenance. Standard dished heads are readily available, and fabricators are equipped to roll the required longitudinal sections.

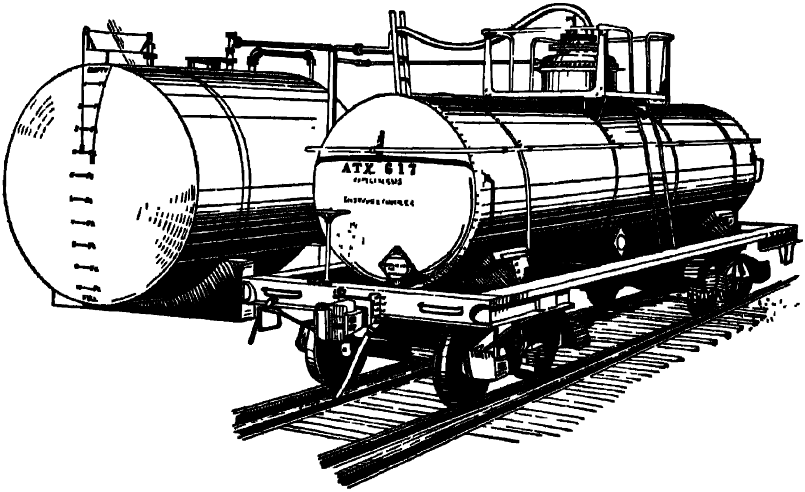

FIG. 11-38. Typical storage tank.

The vertical cylindrical type is usually supplied with a flat bottom, and the cover, if any, is usually of the flat removable type. This type of construction is not suitable for pressure discharge. It is, however, of simple construction, and for smaller sizes up to 10,000 gal is very common. It is readily handled, transported, and installed, although, unless supported on a flat slab, the problem of support may be somewhat complicated In the larger sizes, this type of tank lends itself to field erection, the principal problem being to provide a self-supporting cover for the large diameters Tanks 20 by 20, 30 by 30, and 40 by 40 ft erected and rubber-lined in the field are not uncommon.

Process Tanks. For numerous types of process tanks rubber lining is recognized as standard equipment. While it is not possible to describe each instance in detail, some of the principal uses are as follows:

Plating Tanks (Fig. 11-39). For plating-tank service rubber has several important characteristics. In the first place, most plating is done from an acid solution, and rubber provides the necessary resistance to chemical corrosion. In the second place, rubber being a nonconductor, prevents current leakage. In the third place, rubber prevents metallic contamination, such as might readily occur if metallic linings were used. It is of course important that the rubber contain no materials which can be leached out by the solution and which would poison the bath and brittle, discolor, or otherwise affect the quality of the plate. The rubber must also be of proper and uniform density and composition to prevent plating through, with resultant deposition of the metal on the surface of the rubber. Plating tanks may be of any size or design, and the design detail may include rubber-covered anode supports, overflow troughs, piping connections, etc.

Pickling Tanks (Fig. 11-40). Pickling is usually accomplished by immersion of metal in a hot-acid bath (235°F maximum) and is severe service not only on account of high temperature but also on account of the possibility of mechanical abuse. Rubber-lined steel tanks protected with inner linings of acidproof brick and cement are commonly used in this service. The steel tank provides a shell of adequate strength and rigidity. The rubber lining protects the steel against the corrosive action of the hot acid, and the brick lining protects the rubber from the excessive temperature and mechanical abuse. If high temperature and possibility of mechanical abuse are not present, inner brick linings are not required. Various sizes and types of rubber-lined pickling tanks are in service, varying from small batch tanks to large multiple tanks placed in series for continuous pickling operations.

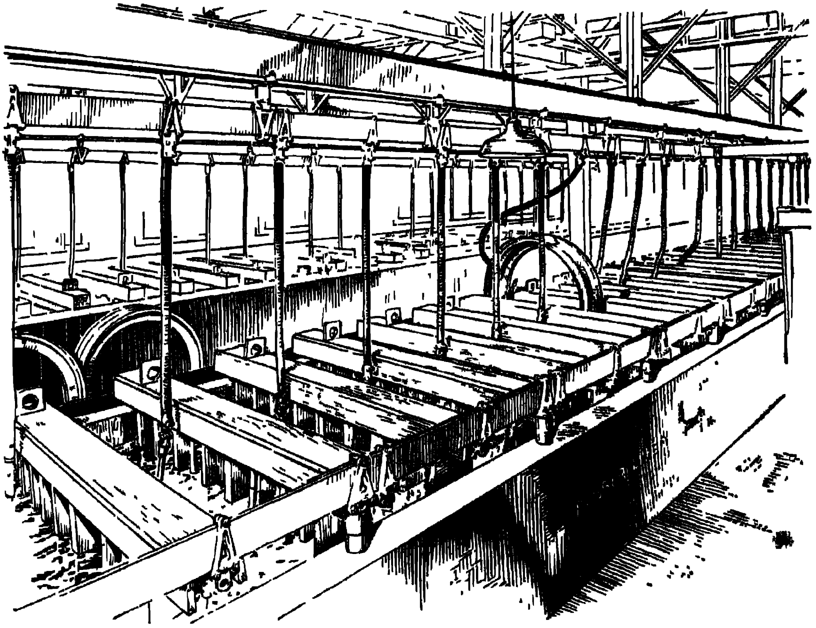

Fig. 11-39. Plating tank.

Bleach Tanks. Rubber linings have excellent resistance to chlorine and to bleach solutions, and rubber-lined tanks are used extensively in batch and continuous bleach operations. These tanks will vary in size and design in accordance with requirements. An outstanding application is the use of vertical cylindrical tanks, approximately 15 ft diameter by 60 ft high, in use in connection with the continuous bleaching of paper pulp.

Ion-interchange Tanks. Many ion-interchange tanks are rubber-lined owing to the fact that either the solution being treated is corrosive, or acid backwash is necessary to revivify the interchange agent. Conspicuous examples are in the treatment of sugar solutions, formaldehyde, and water purification.

Evaporators and Crystallizers. In recent years there has been a very considerable increase in the use of rubber linings for evaporators and crystallizers, particularly for the recovery of salts from waste solutions. Rubber linings are admirably suited for this service, having adhesion adequate to withstand full vacuum and the corrosive effect of the solution and further providing excellent abrasion resistance at the point of discharge.

Crystallizing Tanks. Rubber-lined crystallizing tanks are in common use for the separation of crystalline materials from corrosive mother liquors.

Mixing Tanks. Rubber-lined mixing tanks are used for the addition of acids to various solutions. In such cases, if commercial 66 Baumé sulfuric acid is used, it should be borne in mind that this material has a high specific gravity and tends to stratify and settle to the bottom of the tank. Strong sulfuric acid has a destructive effect on rubber. Hence in all cases stratification must be prevented by air or mechanical agitation. Also, the addition of strong sulfuric acid results in liberation of considerable heat, and steps should be taken to keep the maximum temperature within reasonable limits.

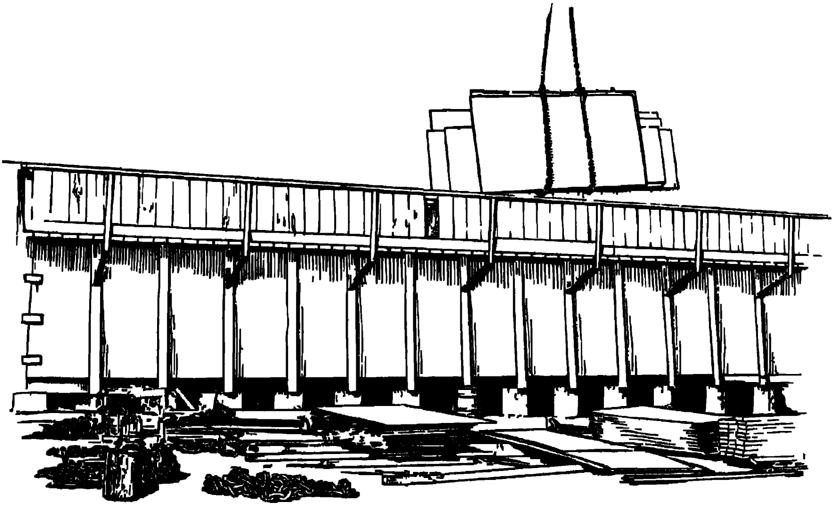

Fig. 11-40. Batch pickling tank.

Scrubbing Towers (Fig. 11-41). Rubber-lined scrubbing towers are frequently used for the absorption of soluble gases. Perforated grid plates can be furnished for support of coke, tile, etc. As the rubber lining is constantly wetted with a film of solution, the rubber is protected from direct contact with gaseous constituents which might ordinarily be destructive to rubber, with the result that rubber linings can frequently be used for service in scrubbing towers under conditions for which rubber would not normally be considered suitable.

Pipe and Fittings (Fig. 11-42). Rubber linings can be installed in piping of all sizes from 1 in up. Standard wrought pipe is ordinarily used, but rubber lining can be installed in fabricated or spiral welded pipe. In the majority of cases, flanged assemblies are used, although special assemblies such as victaulic joints can be supplied. Ordinarily, ASME Standard 125-lb cast-iron flanges are furnished, although any of the various types of steel flanges can be supplied. Welded-on steel flanges are preferable for vacuum service. Rubber lining can also be installed in special bent sections, fabricated manifolds or headers, and other special fabricated sections. Not all such fabricated sections can be handled as there are certain limitations to degree and extent of bends, length, and location of side outlets, etc., which will be discussed below under Engineering Considerations. Several types of rubber-lined valves are available, including gate valves, diaphragm valves, check valves, etc.

Special Equipment (Fig. 11-43). Rubber linings and coverings are adaptable to many types of process equipment, including fans, pumps, continuous filters, filter plates and frames, agitators, screw conveyors, centrifugals, etc. It is good practice to purchase special equipment complete from the equipment manufacturer. He is in better position to make recommendations as to the design, size, etc., required for a given performance. He is better able to modify design for incorporation of rubber if such modification is necessary. If special machining is required, he would have the necessary equipment to provide such machining. If dynamic balance were necessary, he would be able to provide it. The rubber manufacturer's liability is limited to workmanship and material and does not include responsibility for mechanical performance subsequent to rubber covering. The rubber manufacturer should, of course, confer with the equipment manufacturer as to the proper type of stock for the given service conditions. Rubber-covered equipment of each of the types enumerated above is operating with entire satisfaction under a wide variety of service conditions.

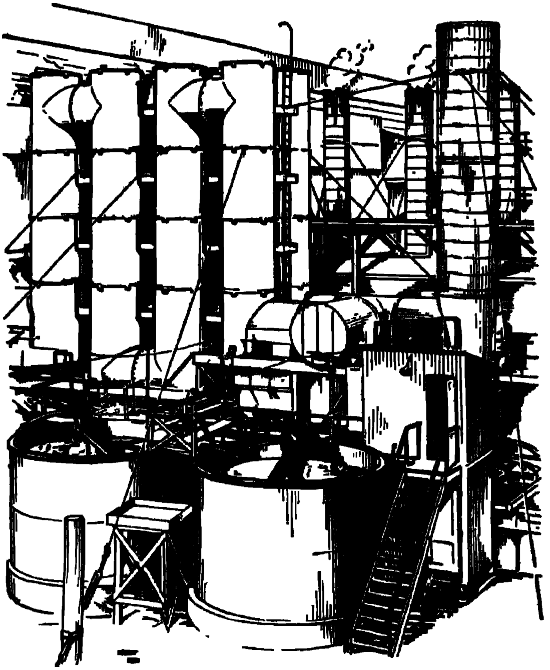

Fig. 11-41. Scrubbing towers and process tanks.

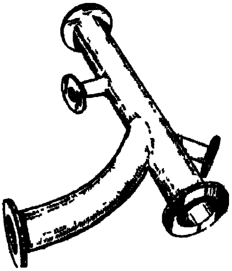

Fig. 11-42. Special fabricated assembly.

Transportation Equipment. Rubber-lined equipment is extensively used for the bulk transportation of corrosive liquids. Rubber-lined tank cars are standard for many services. In all cases, the rubber lining must conform to ICC Specification 103-B for riveted cars and to ICC Specification 103-BW for welded cars, and in each case the rubber manufacturer is required to give the owner a certificate stating that the rubber lining properly conforms to the ICC specification. Rubber-lined truck tanks and rubber-lined barge tanks are also in common use, and if these are engaged in interstate commerce, the rubber manufacturer must also certify that the rubber linings conform to the ICC requirements.

Auxiliary Equipment (Fig. 11-44). In connection with many of the items described above, auxiliary equipment such as covers, hoods, ventilating ducts, grid plates, baffles, stacks, etc., are required. It is common practice to rubber-line and rubber-cover these various items.

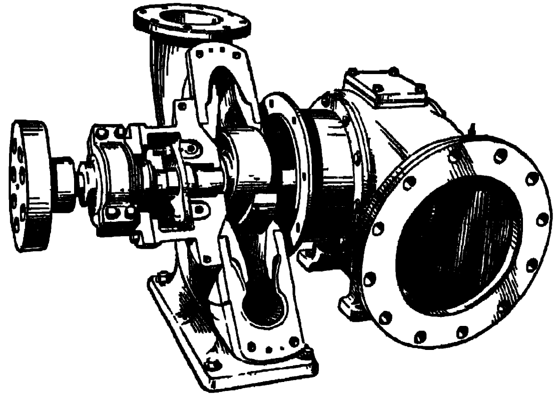

FIG. 11-43. Centrifugal pump.

Thickness of Rubber Lining for Most General Requirements. Standard thickness of rubber lining is $\frac{3}{16}$ in. For severe service conditions or where abrasion is present, $\frac{1}{4}$-in. thickness is recommended, and in certain cases additional thicknesses have been provided. For pipe and fittings up to and including 5-in. diameter, $\frac{1}{8}$-in thickness is standard. For larger sizes, 6-in. and above, $\frac{3}{16}$-in. thickness is recommended. For particularly severe conditions, $\frac{1}{4}$-in. linings should be used.

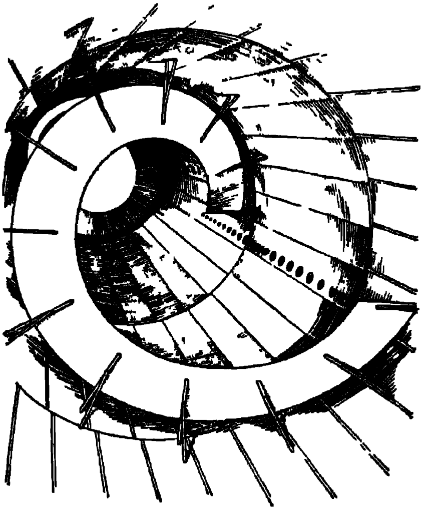

FIG. 11-44. Exhaust duct.

ENGINEERING CONSIDERATIONS

Only special considerations as applying to rubber-lined equipment will be considered. It is understood that, in so far as metal parts and construction are concerned, all details of standard engineering practice will apply and will be provided for.

Tanks. *Pressure Tanks.* In so far as rubber lining is concerned, installation is not ordinarily complicated by pressure consideration.

Vacuum Tanks. If vacuum vessels are to be rubber-lined, it is essential that the steel vessels be airtight. If the vessel is airtight, no difficulty will be experienced with rubber lining. If the metal is not airtight, the rubber lining will blister and pull away from the metal. All vacuum vessels should be vacuum-tested by the fabricator prior to installation of the rubber lining and should be certified. Vacuum test may be applied subsequent to rubber lining, but this is not ordinarily considered necessary if the vessel itself has been pretested. Furthermore, if hard-rubber linings are used, a test of considerable duration is necessary to demonstrate positively any weakness in the construction.

Brick-lined Tanks. If rubber-lined tanks are to be brick-lined, it is essential that adequate provision be made in the brick lining to compensate for expansion and contraction of the brickwork. It is also essential that the steel tank be so designed as to have adequate strength to withstand the stresses set up by expansion of the brick wall. If long tanks are involved, it is preferable that sections be welded together, subsequent to erection if necessary, rather than to rely on bolted flanged joints. Extreme care in design of steel and brickwork is particularly essential if tanks are subjected to low external temperature during operation.

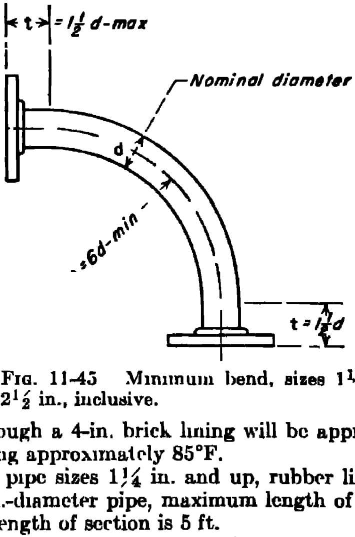

Fig. 11-45 Minimum bend, sizes 1¼ to 2½ in., inclusive.

Temperature Gradient. If temperature of liquid in tank is 212°F and room temperature is 70°F, the temperature drop through a 4-in. brick lining will be approximately 60°F and through an 8-in. brick lining approximately 85°F.

Pipe and Fittings. *Pipe Sections.* For pipe sizes 1¼ in. and up, rubber lining can be installed in 20-ft sections. For 1-in.-diameter pipe, maximum length of section is 10 ft, and for ¾-in. pipe maximum length of section is 5 ft.

Bent Sections. Within limits, rubber linings can be installed in bent sections. From a manufacturing standpoint, the essential feature is that it must be possible to see and to reach all surfaces to be rubber-covered in order to assure uniform bond, absence of blisters, etc. While it is not possible to establish any hard and fast rules, it is possible to indicate the approximate [illegible] Figures 11-45 to 11-47 indicate the safe minimums. If doubt exists as to the possibility of rubber-lining bent sections, the problem should be referred to the rubber manufacturer.

Fabricated Headers. Space considerations, reduction in the number of flanged joints, ease of installation, or other factors often make the use of fabricated headers, manifolds, or other special fittings with side outlets desirable. It is possible to rubber-line many such constructions. Here again, it is not possible to establish any hard and fast rules. The comments given above with regard to visibility and accessibility of areas to be rubber-covered apply. Also, it is possible to give some indication as to maximum limits, which are detailed in Figs. 11-48, 11-49, and 11-50. Again, constructions involving doubt as to the possibility for rubber lining should be referred to the rubber manufacturer.

Flange Construction. Details of handling rubber lining over flange faces will vary somewhat with different manufacturers. With soft-rubber linings, rubber may be brought out over full face of flange or may be brought out to the inside of boltholes

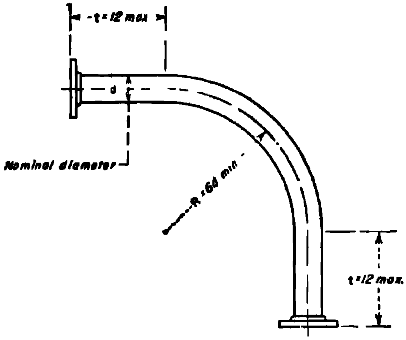

Fig. 11-46. Minimum bend, sizes 3 in. and over.

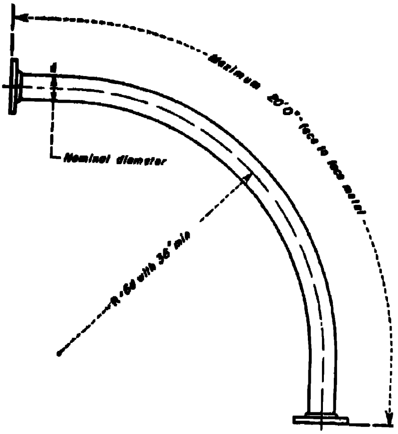

Fig. 11-47. Minimum bend, bar length, sizes 3 in. and over.

only. With the latter construction, noncompressible ring gaskets are used. This construction has the advantage that maximum compression which can be applied to the rubber lining is definitely limited. Figure 11-51 illustrates this construction. With hard-rubber lining, the rubber is brought out over the full face of the flange, and assembly is made with pure-gum soft-rubber gasket. It is important that soft gaskets be used in order to prevent damage to the rubber lining. It is also important that the gaskets be cut to proper size. Figure 11-52 details hard-rubber-lined flange assembly and proper gasket specifications and dimensions.

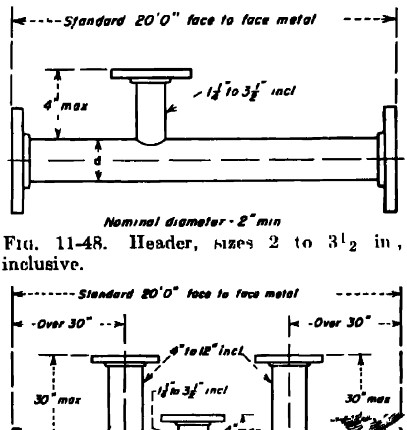

Fig. 11-48. Header, sizes 2 to $3\frac{1}{2}$ in., inclusive.

Gaskets. Necessary assembly gaskets for either soft- or hard-rubber linings are normally supplied by the manufacturer and are included in the purchase price. It is important that these gaskets be used for installation.

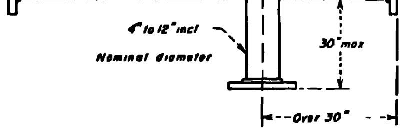

Fig. 11-49. Header, sizes 4 to 12 in., inclusive.

Pressure Limitations. Hard-rubber-lined flanged assemblies can be recommended for 200 lb maximum pressure. Soft-rubber-lined flanged assemblies are suitable for pressures up to 600 lb maximum. Special joints such as victaulic are also suitable for pressures up to 600 lb maximum and possibly for higher pressures under certain circumstances. It is recommended that manufacturers be consulted for recommendation if use of rubber-lined piping under high pressures is contemplated.

Vacuum. Rubber-lined piping for vacuum service is satisfactory provided metal parts are airtight. It is recommended that welded-on steel flanges be used if service under vacuum is required.

Pressure Drop. No comparative test figures are available for pressure dropped through rubber-lined piping as compared to piping of other materials. Experience shows, however, that, if calculations are based on coefficient for new steel pipe, calculations will be sufficiently accurate for installation requirements.

Specification of Section Lengths. As rubber lining is brought out over flange faces, allowance for it must be made in predetermining the lengths of the individual pipe sections. Allowance must, of course, be made for each joint whether of pipe sections or of fittings. In ordering rubber-lined piping, it is usually better to specify the desired over-all length of each section, leaving it to the rubber manufacturer to make proper allowance for lining and gasket. Purchaser can, of course, predetermine exact metal length should he so desire, but in such cases, proper joint allowance should be obtained from the selected rubber manufacturer as specifications of different manufacturers vary slightly, and it is important that proper allowance be used.

FIG. 11-51. Flange construction, soft-rubber lining.

Allowance for Expansion and Contraction. It is important, particularly with large-diameter piping or where long runs are involved, that provision be made in installation to compensate for expansion and contraction. Stress is, of course, transmitted to the rubber over the flange faces, and it is important that this stress be held below the maximum allowable for the material. Requirements will vary depending upon whether soft- or hard-rubber linings are used.

Stress in Soft-rubber Linings. If it is desired to use spring in the line to compensate for temperature changes, the line may be computed as a square corner unit. (The Mitchel method is sufficiently accurate for the temperature changes encountered.) Due consideration must be given to the weight of the pipe and resistance to bending afforded by the supports. In the case of soft-rubber linings, steel stresses should not exceed those specified in Code for Pressure Piping, American Tentative Standard. If construction described above employing noncompressible gaskets is used, it should be remembered that centroid of eccentric thrust under bending movement is moved outward on to noncompressible gasket.

Stress in Hard-rubber Linings. With hard-rubber linings, the limiting value of pressure to ensure absence of shear on inner face of flange due to plastic flow and tightness after permanent set of soft-rubber gasket should be 300 psi on periphery of flange. This corresponds to stress in steel, figured as continuous tube, of 5,000 psi. This stress limitation will ensure that the original bolting pressure will not be exceeded and will eliminate loosening of joint and possibility of cracking of rubber at inner face.

Relief of Strain. Strain due to expansion and contraction must be relieved. In the smaller sizes for two- or three-dimensional layouts, no great strain may be present because of springing in the line, but straight runs between fixed dimensions must allow for thermal changes. This may be done by means of expansion joints, several types of which are available. Where relief is required in two- or three-dimensional lines, this may be obtained by the use of a section of flanged wire-reinforced hose. The bend in the hose should be uniplanar. The hose manufacturer should be consulted as to proper length and specification. Each length is a separate layout problem, depending upon amount of movement in the line, angle of intercept, and other service conditions.

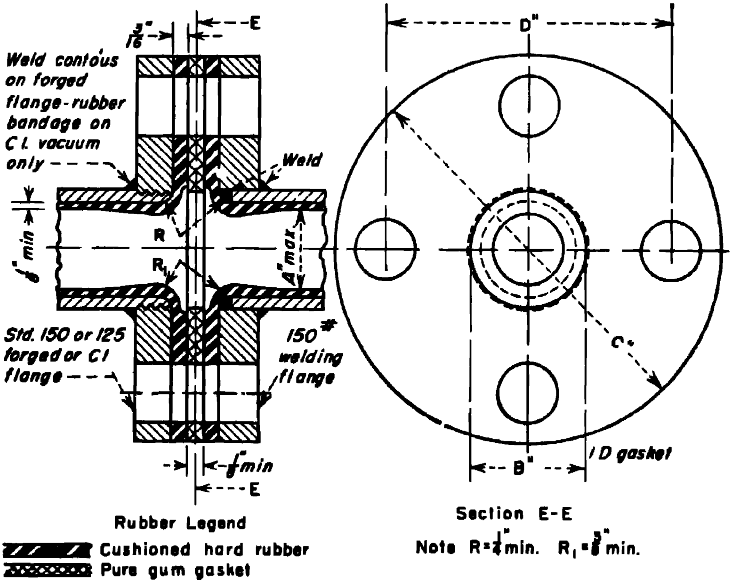

Fig. 11-52. Flange construction, hard-rubber lining.

Installation. It is important that reasonable care be exercised in the handling and installation of rubber-lined piping. Piping should be protected from oils and rubber solvents and from extreme rapid changes in temperature. Rubber-lined piping should first be brought to proper elevation and alignment so that flange is parallel to companion flange. Gaskets as recommended and supplied by the rubber manufacturer should be used. Bolts should be inserted and brought up evenly all around, using standard-length spud wrenches for the size of bolt installed without extension arm or hammer. After assembly, tests should be made with noncorrosive liquid at working pressure and the line inspected for tightness. If any particular joint requires excessive tightening, it should be opened and examined for the cause of the difficulty. Lines should be watched closely for leaks during the first week of service and bolts tightened where necessary. Inspections should be made at regular intervals thereafter.

Supports and Anchors. Supports should be designed to eliminate torque and excessive bending and to allow for deformation under temperature change. Tension due to bending is eliminated by proper anchorage and bends. Compression due to thrust should be minimized by expansion joints. Torque can be eliminated by proper blocking along line of thrust. Each piece of pipe should have an adjustable support, and any piece over 12 ft long should have two supports. Hangers should be long enough to allow for movement without undue restraint when spring in line is relied upon for temperature correction. Roller supports or roller hangers are preferable; where vibration is present and hard rubber is to be used, especially at low temperatures, spring hangers should be used with lock washers under the flange bolts. Spring hangers should also be used on large-size line where there is danger of buckling due to uneven temperature at top and bottom of line. This may occur especially in lines subjected to intermittent service at partial capacity with high temperature differential between the liquid and the outer atmosphere.

Special Equipment. If machining of special parts is required subsequent to rubber covering, this is usually best accomplished by the equipment manufacturer. Hard-rubber and semihard-rubber stocks are available which have proper machining qualities.

High-speed equipment, such as fans, centrifugals, etc., should be checked for dynamic balance subsequent to rubber covering. This is best accomplished by the equipment manufacturer on the same equipment used by them for initial dynamic balance. Small balancing pads are commonly vulcanized integral with the main rubber covering, and dynamic balance can be adjusted by cutting away a portion of this rubber pad. The equipment manufacturer should also be responsible that the design is such as properly to accommodate the rubber and that the construction is adequate to handle the extra weight introduced by the addition of the rubber covering.

CARE OF RUBBER-LINED EQUIPMENT

Users of rubber-lined equipment should observe the following simple rules for care and maintenance:

1. All rubber-lined equipment should be inspected at regular intervals.
2. Rubber linings should be protected from oils, greases, and rubber solvents.
3. Rubber linings should also be protected against mechanical abuse. Hard-rubber linings, particularly at low temperatures, should be protected against hammer or other external shock. If necessary to enter a tank by means of a ladder, the feet of the ladder should be protected with burlap or similar material. Inspectors should preferably wear rubber shoes. Measuring sticks should have blunt ends to prevent damage to rubber. Care should be taken not to drop sample bottles into rubber-lined tanks.
4. Inspection lamps should have proper guards. Under no circumstances should a bare light bulb be allowed to remain in contact with the rubber.
5. Hard-rubber linings should be protected against thermal shock. Steps should be taken to ensure gradual heating or cooling.
6. If it is necessary to keep rubber-lined tanks or piping out of service for considerable periods, it is better to fill them with dilute hydrochloric acid solution, care being taken to protect solution against freezing.
7. Rubber-lined equipment should not be transferred from one service to another without checking with rubber manufacturer as to the suitability of material to proposed change.
8. Certain solutions such as ferric chloride tend to coagulate in cold weather. Whenever necessary to warm solution to permit its removal, such warming should be gradual and should be continued only to minimum point required for liquefaction.
9. Exposed metal surfaces should be carefully protected against corrosion.
10. Necessary repairs should be made immediately to prevent extension of damage to rubber or metal.

ELECTRIC WELDING IN PLANT DESIGN, OPERATION, AND MAINTENANCE

BY CHARLES G. HERBRUCK

Assistant Secretary, The James F. Lincoln Arc Welding Foundation, Cleveland, Ohio

Electric welding is a process of fusing metal through the application of heat that is produced by electricity. Since its first practical applications during the First World War, developments and refinements in techniques and equipment for welding have produced a process that is basically simple, yet highly versatile. In every industry that uses metal, welding has become an important tool of plant management. Welding is one of the basic tools in such work as building new structures or repairing or enlarging existing structures, installing or maintaining piping systems of all kinds, the fabrication of sheet metal into containers, tanks, ventilating ducts, and other conveniences, repairing broken machinery parts, restoring worn parts by building up the wearing surfaces, making replacement parts for broken castings, and the building of special machinery and equipment.

There are two general classifications of electric welding processes: electric arc welding and resistance welding. Electric arc welding is the process most useful in plant operation and maintenance. Resistance welding is chiefly employed in production operations. Its use is limited by the nature of the process and the equipment required. The data in this section, therefore, will deal largely with the techniques and applications of arc welding.

RESISTANCE WELDING

Resistance welding is the process of joining two or more metallic parts to form an assembly, the heat for the formation of the weld being created by the electrical resistance of the pieces being welded when electric current is supplied by the welding machine. Simply stated, it is a heat and squeeze process The parts to be welded are heated to point of fusion by the passage of electric current through them. When the welding heat has been reached, pressure is applied mechanically and the electric current is broken. This mechanical pressure and heat, generated by the electric current passing through the resistance of the materials being welded, melts and fuses the faying surfaces of the two parts. As the metal cools, the weld is formed.

The heat being generated in the weld is expressed by the formula

$$W = I^2Rt$$

where W is heat in watt-seconds, I is amperes flowing through the weld, R is the resistance in ohms, and t is the time in seconds. Thus, resistance factors affecting the amount of heat being produced by a given welding current for a unit of time are

1. The electrical resistance of the materials being welded
2. The contact resistance between weldments as determined by surface condition, scale, welding pressure, etc.

A great many types of metals have been satisfactorily welded with this process. Weldability is determined by the electrical resistance of the metal. Low-carbon steel is easily welded, while copper and aluminum present some difficulties.

The most important types of applications in the field of resistance welding are spot welding, butt welding, flash welding, and seam welding. The spot weld is made by overlapping the parts and gripping the overlapped sections between two electrode points through which the current is passed and pressure applied to make the weld in a single spot. The butt weld places the parts to be welded end to end, to be electrically heated and squeezed together. The flash weld is an adaptation of the butt weld.

The seam weld is similar to the spot weld except that a circular rolling electrode is used to produce the effect of a continuous seam. A special spot welding operation known as "shot welding," employing carefully controlled short time intervals and high currents, is often used for special alloys such as the "stainless" group.

Because of the requirements of special equipment and the critical control that must be maintained, resistance welding is best suited to mass-production operations in sheet metal less than ¼ in. in thickness. Its limited use in plant operation does not generally warrant the purchase of equipment for that purpose only.

ELECTRIC ARC WELDING

Arc welding is the process of fusing metal through the heat generated by an electric arc. The process has been developed and refined extensively, and today there are a number of methods of employing the arc in welding. The metallic arc process is the one which has the widest general use in plant operation and will, therefore, receive major treatment here. Before discussing the metallic arc, some of the other methods should be given brief consideration:

Atomic-hydrogen Arc Welding. In the atomic-hydrogen welding process an arc is established and maintained between two tungsten electrodes, while a stream of hydrogen gas is passed through the arc. As this hydrogen reverts to molecular form in the arc, an intense heat is given off which is used to fuse the metal being welded. The process is much the same as welding with a gas torch, and while it is more costly than other processes, it has some advantages in welding thin sheets where a high finish is required. A filler rod is used when extra weld metal is needed.

Inert-gas Arc Welding (Helium, Argon). This process is similar to atomic-hydrogen welding. It differs in that a single tungsten electrode is used to form the arc directly between the electrode and the base metal, and the inert gas is used only for protection, not heat. A filler rod is used, and the inert gas supplied through an annular opening in the insulated tube surrounding the electrode protects the metal during the welding.

Carbon Arc Welding. In this process the arc is formed between the work and carbon electrode. It is a puddling operation and cannot be used in vertical or overhead welding. The heat of the arc between the carbon and the work melts a small pool which is kept molten by playing the arc across it. A filler rod is used to add extra metal. The carbon arc is used successfully in welding aluminum and copper, and can be used economically as a cutting tool where a smooth cut is unnecessary.

Metallic Arc Welding. In the metallic arc process the current, either alternating or direct, which is generated in the welding set, is used to create an arc between a metallic wire and the work to be welded. The intense heat of the arc itself, which is said to be the hottest known commercial source of heat, brings the work to the melting point almost instantly. The end of the wire is also melted, and the tiny globules of metal formed on the tip of the wire are forced across the arc. These globules and the molten base metal combine and, when cool, solidify into a homogeneous mass. The globules of metal are actually forced across the arc stream and not merely dropped by gravity. It is this arc force which makes overhead welding possible with the metallic arc process.

Practically all welding with the metallic arc is done with what is called the shielded arc. In shielded arc welding the metal wire, or electrode as it is called, is covered with a chemical coating. In the heat of the arc, this coating burns and melts and forms a cloud of protective gas, completely enveloping the arc and molten pool in the base metal. The coating also creates a slag which protects the weld during cooling. The coating and the cloud and the slag which are formed by it have several functions which improve the quality of the welds made. The coating controls the chemical analysis of the weld by preventing the vaporization or oxidation of essential elements, such as manganese; in some cases additional elements not present in the core wire can be added by means of the coating. The primary purpose of the coating, however, is to form the protective atmosphere, and the slag, which acts as a fluxing agent, controls cooling rates and the shape of the bead and protects the weld from harmful oxides and nitrides present in the ambient atmosphere. The coating also provides better arc characteristics such as ease in striking and maintaining the arc, increased speeds, and better penetration (see Fig. 12-1).

Welds made with a shielded arc on mild steel have a tensile strength of 60,000 to 75,000 psi, which is 20 to 50 per cent higher tensile strength than possessed by welds made with an uncoated electrode. The ductility of welds made with a shielded arc averages 100 to 200 per cent greater than those made with a bare electrode. The resistance to corrosion of shielded arc welds is greater than mild steel itself.

Equipment. The chief quality desired in welding equipment for general plant use is flexibility. A welding set that generates d-c welding current will be found to have the widest range of applications. These motor-generator sets are available powered either by alternating or direct current or internal-combustion engines. The set should be easily portable. A unit with a NEMA rating of 200 amp will provide adequate capacity for all general plant work. Sustained welding in heavy plate, such as might be met in structural work or production work, would demand a 300-amp unit. There is a very limited amount of this type of welding in maintenance operations.

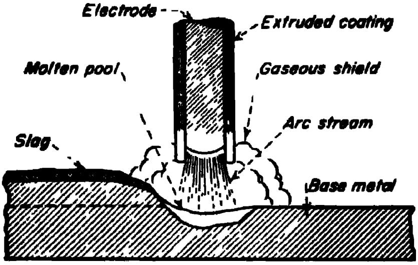

FIG. 12-1. Shielded arc in the process of arc welding.

Material to be welded generally must be formed and cut to the proper shape. A certain amount of other basic machinery therefore is necessary for welding operations. Cutting torches, saws, shears, brakes, and a drill press may be needed, as well as the other small tools generally found in the millwright section of every plant.

Protective clothing should be provided to protect the operator from heat and flying sparks. Leather gloves, apron, sleeves, and shoe covers are suggested where a considerable amount of welding is to be done. Electrode holders, face shields, cable, and a variety of electrodes must be all available wherever the process is used. The arc should not be looked at with the naked eye at any distance closer than 40 ft The infrared and ultraviolet rays from the arc can cause temporary discomfort. The eye burn from the arc rays will not cause permanent injury. In case of burn, the eyes should be washed every few hours with sweet oil. Some shield should be provided, either a portable screen or a permanent enclosure, in rooms where the welding operations are performed.

Welding operators for general plant work should be good general all-around welders. They should be trained in fundamentals of welding as well as a wide variety of techniques. It is well for operators to be familiar with blueprint reading, basic welding metallurgy, use of welding symbols, and other allied subjects. A mechanic who is used to working with tools generally requires only a few hours of training to be able to hold an arc and deposit a satisfactory weld for simple applications. Experience and imagination gradually build an operator to the point where he can perform difficult applications and develop the full possibilities of using welding.

Welding is a basically simple process and easy to understand. Its constantly expanded use over the past 25 years has accumulated a fund of information that appears to be complex and confusing to the person first approaching the subject. The process, however, requires only a minimum of equipment and training to be first applied, and the fuller understanding of its uses comes as its use is extended.

TECHNIQUES OF WELDING

In the case of welded joints in mild steel, which comprise roughly 95 per cent of all welding, the weld is actually stronger and has a much higher elastic limit than the plates joined. Therefore, a weld correctly made will never fail in actual service, as the failure will first occur in the structure itself. This can only be said, however, of welds that have been correctly designed and properly made.

The various technical and engineering societies have established codes that prescribe proper welding techniques for making good welds in the various classes of work such as structural, pressure vessels, piping, ships, etc. The following material will undertake a consideration of the general factors that are the basis for the various codes. The codes should be followed where the requirements of the work warrant it. An understanding of these basic factors is essential to interpreting the codes.

Good welds are the result of the proper selection of

1. Type of joint
2. Type and size of electrode
3. Welding procedure
4. Base metal of good weldability

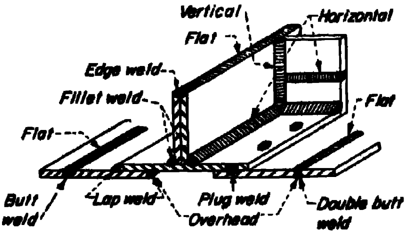

Fig. 12-2. Composite view of types of welded joints and their location.

Types of Welded Joints. The selection of the type of welded joint to be used in a particular application is governed by three factors:

1. The load and its characteristics; *i.e.*, whether the load is in tension or compression, and whether bending, fatigue, or impact stresses in any combination are present
2. The manner in which the load is applied, *i.e.*, whether load application is steady, variable, or sudden
3. The cost of the joint preparation and welding

The selection of the proper joint for economical welding is important in designing structures, machinery, or equipment. Maintenance welding on the other hand frequently allows no choice of joints. Understanding the principles of good joint selection is important, however, to safe and economical welding practices in all applications.

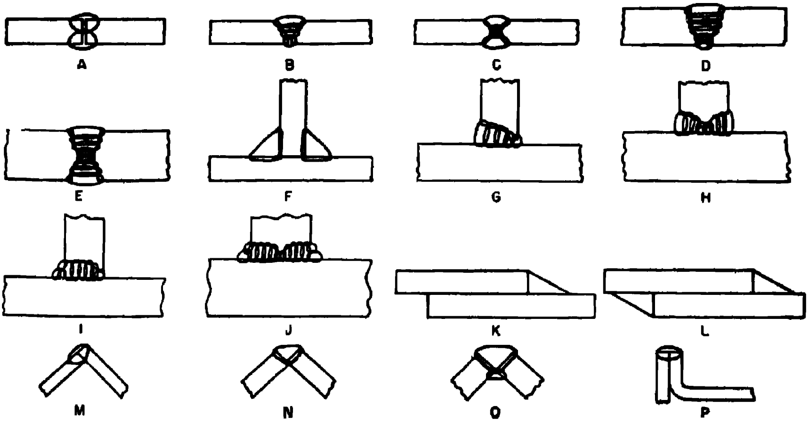

Fig. 12-3. Types of welded joints and variations. (*A*) Square butt joint,* (*B*) single-V butt joint,* (*C*) double-V butt joint,* (*D*) single-U butt joint, (*E*) double-U butt joint, (*F*) square T joint,* (*G*) single-bevel T joint,* (*H*) double-bevel T joint,* (*I*) single-J T joint, (*J*) double-J T joint, (*K*) single-fillet lap joint,* (*L*) double-fillet lap joint,* (*M*) flush corner joint, (*N*) half-open corner joint, (*O*) full-open corner joint, (*P*) edge joint.*

The classification of joints and their common names are shown by Fig. 12-2. A brief discussion of the joints most commonly used in maintenance welding and their application to given service conditions follows:

The square butt joint (Fig. 12-3.1) is suitable for all usual loads and requires full and complete fusion, particularly when load is of fatigue or intermittent nature. The base metal for this type of joint must be good weldable steel since a large portion of the base metal is melted during the welding. The thickness of plate on which the square butt joint is used is generally ⅜ in. or lighter although this type of joint has been used on other plate sizes. Preparation for welding this joint is simple, requiring only a matching of the edges of the plate, separated by a distance dependent upon the plate thickness. Because of the simple preparation, the square butt joint is low in cost.

---

* Joints most commonly used in maintenance welding.

The single-V butt joint (Fig. 12-3*B*) is suitable for all usual load conditions. It is generally used with plate thickness considerably greater than the square butt joint—⅜ in. or heavier—although its use on thinner plate is not unusual. Preparation is more costly than the square butt joint, and more electrode is used in welding.

The double-V butt joint (Fig. 12-3*C*) is suitable for all usual load conditions. It is used for plates of greater thickness than the single V and for work which can be welded from both sides. Cost of preparation for welding is higher than for single-V butt joint, but double V requires approximately half as much electrode. Cost of machining should be weighed against the cost of welding and the joint selection made accordingly. Warpage can be reduced by alternating the beads, welding on one side and then the other to keep joint symmetrical during welding.

The square T joint (Fig. 12-3*F*) corresponds to the square butt joint in that no machining of plates is required. The square T is used for all ordinary plate thicknesses, principally for loads that place the welds in longitudinal shear. For severe impact or heavy transverse loads, the nonuniform stress distribution of the joint should be kept in mind and the stress intensity of the application duly considered. The square T requires considerable weld metal, and therefore the welding cost may be higher than other types of T joints.

The single-bevel T joint (Fig. 12-3*G*) is suitable for much more severe loads than the square T, owing to its better distribution of stress. It is employed in most instances for welding plates ½ in. or thinner in work that can be welded from one side only. While more costly to machine than the plain T, the single-bevel T joint is lower in electrode costs.

The double-bevel T joint (Fig. 12-3*H*) is suitable for heavy loads in longitudinal or transverse shear in joining heavy plate where welding can be done from both sides. Double bevel is somewhat higher than single-bevel T joint in machining cost but has lower electrode cost than some other types such as plain T.

The single-fillet lap joint (Fig. 12-3*K*) is frequently used and has the advantage of requiring practically no machining to fit the edges of the plate. When fatigue or impact loads are encountered, stress distribution should be carefully studied. Where loading is not too severe, the single-fillet lap joint is suitable for welding plate of all thicknesses.

The double-fillet lap joint (Fig. 12-3*L*) is suitable for load conditions much more severe than can be met by the single-fillet lap joint. In general, the two fillets should be full size, although one fillet may be smaller than the other in some instances. Because of its lower cost, the double-fillet lap joint is widely used. For extremely severe loads, the butt joint should be used.

The edge joint (Fig. 12-3*P*) is used in joining plates ¼ in. or thinner for light load . Careful consideration must be given to the load conditions, especially impact and fatigue, as this type of joint is not suitable for severe loads.

Selection of Electrodes. There are two aspects of the question to consider in deciding which electrode to use: the general type of wire and the proper size diameter of wire. The selection of the correct size of wire will be considered under Arc Speed The following material indicates information that must be known for selecting the proper type.

To tabulate a guide for correct selection of electrode for all the innumerable combinations of various conditions is impractical. Each job must be analyzed and the following factors weighed in relation to each other for their relative importance

1. The position in which the work must be welded
2. The type and thickness of the base metal being used
3. The preparation of the work, which affects fit-up
4. The type of available welding current

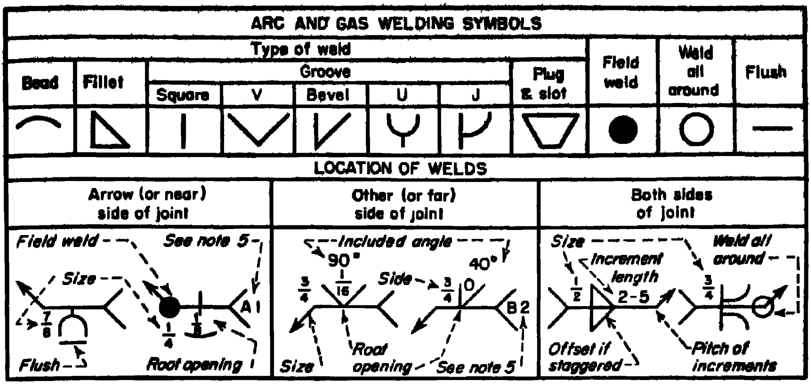

FIG. 12-4. Legend for use on drawings of symbols to indicate type of weld as specified by American Welding Society.

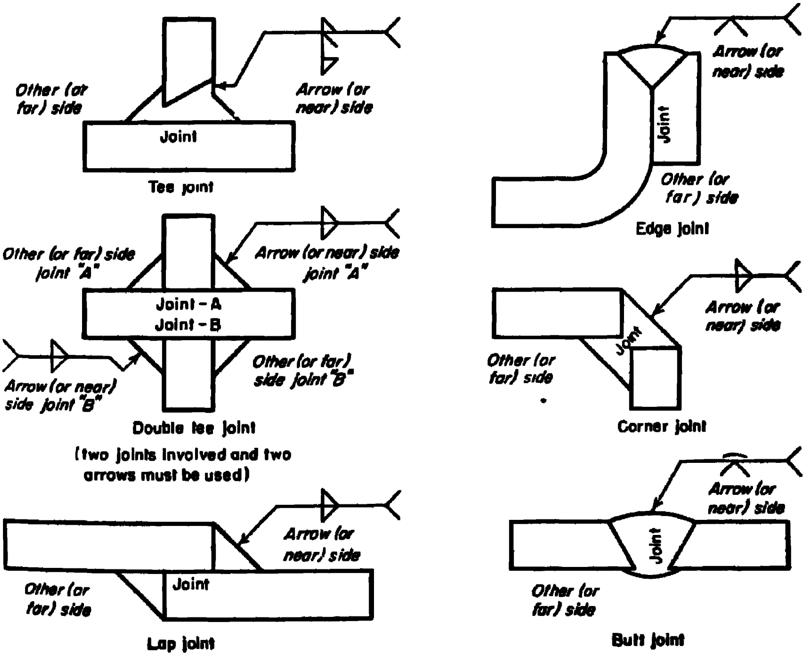

FIG. 12-4A. Location of line of joint in the various fundamental types of joints.

5. The class of work, *i.e.*, whether deep penetration or surface quality is the chief essential

The American Welding Society has established specifications for the manufacture of electrodes which have become the standard in the industry. Manufacturers publish complete information on the composition of their electrodes and the correct procedure for their use in compliance with AWS specifications. All this information should be readily available for reference, and every plant should be familiar with it.

The American Welding Society published in 1948 new specifications for steel and copper electrodes. These are available in booklet form for mild-steel arc-welding electrodes, low-alloy-steel electrodes, copper and copper-alloy electrodes, corrosion-resisting chromium and chromium-nickel steel welding electrodes. This information is available for reference.

Additional information can also be secured from the various electrode manufacturers on cast-iron, hard-surfacing, and nonferrous electrodes.

Welding Procedures. The varying combinations of welding conditions will influence the determination of the correct welding procedure just as they influence the selection of electrodes. The following material considers the general factors that enter into the development of procedures for all applications. They are

1. Type of welding current
2. Polarity
3. Arc characteristics
4. Arc speed
5. Location of welds in relation to strength requirements
6. Distortion

Direct Current and Alternating Current. Welding can be accomplished efficiently with either alternating or direct welding current. Certain factors may necessitate using one to the exclusion of the other, or in some cases certain advantages may be gained.

The type of work being welded should be carefully studied to determine whether alternating current or direct current is better suited to the job. Many stainless steels, low-alloy high-tensile steels, and nonferrous metals cannot be readily welded with alternating current. For certain types of welding an electrode for use with alternating current will cost 1 to 1½ cents per lb more than a comparable electrode for use with direct current. In sheet-metal work or when smaller diameter electrodes are used, the speed of welding is generally higher with direct current. When larger electrodes, over $\frac{3}{16}$ in., are used with higher currents, alternating current will sometimes increase the speed of welding. Power cost and maintenance costs are generally lower with an a-c machine, but these two factors constitute a small item in anything except production welding.

Polarity. Polarity is of importance only to welding with direct current. The polarity of the welding current is the nominal direction of the flow of current in the circuit and establishes whether the electrode is a positive or negative terminal. The polarity to be used with any particular electrode is established by the manufacturer to control heat balance, *i.e.*, to control whether more heat is produced on the electrode or the work side of the circuit. Manufacturers' recommendations should be followed in all cases. The use of the wrong polarity will result in a substandard performance of the electrode.

With alternating current, since polarity changes very rapidly, the electrode must be suitable for use with either polarity. This does not mean, however, that a negative or positive electrode will not be satisfactory with alternating current. A high-quality electrode may prove satisfactory on both alternating and direct current.

The Arc. Proper control of current and voltage and arc length will result in the proper "heat" for depositing the weld.

The manufacturers of electrodes specify the amperage range of all electrodes for any given size. These recommendations should be followed. In general terms, the amount of current used determines the heat of the arc and the depth to which the base metal will be melted. The thicker the plate being welded, the more heat will be required to secure sufficient depth for the weld, and hence the larger electrodes are necessary.

The arc voltage, which can be controlled in the machine settings, controls the "force" of the arc and should be varied according to the needs of the job. On thin metal, a high voltage is desired, but a low current so that the arc will not burn through the metal. On an overhead job, the essential requirements are high current for penetration yet sufficient arc force to help push the metal up. In welding a casting, the need is for a high current, but the voltage may be low. The best welding machines will, therefore, provide for independent control of voltage and current.

The length of the arc also influences the quality of the weld. An arc that is too long will lose some of its force. The tiny globules of electrode metal tend to form into balls on the end of the electrode and then spatter. The arc stream is not concentrated. The correct length will vary according to the size and type of electrode, the material being welded, and the amount of heat. In general, to control the amount of effective arc force, the electrode should be kept as close to the work as possible, even dragging the electrode along ahead of the molten pool, just keeping the coating lightly touching the plate.

FIG. 12-5 The effect of slow travel speed (*top*) and fast travel speed (*bottom*) on penetration in a 60-deg V-groove weld

Arc Speed. The arc should be moved along the joint to be made with the greatest speed at which the surface appearance of the weld still remains satisfactory. Keeping the tip of electrode moving ahead of the molten pool at high speeds gives the force of the arc full opportunity to dig into the root of the joint. If the travel speed is too slow, the force is dissipated in the molten pool as it runs under the arc (see Fig. 12-5).

Proper speed thus results in deeper penetration into the root of the joint which in turn permits strong welds to be made with the deposition of less metal. A weld can be made either by piling up metal on the outside of the joint or penetrating deeply into the parent metal. Both welds will be equally strong, but the one made by penetrating deeply will be of much lower cost.

This essential arc speed can be obtained by giving proper attention to several factors.

1. The use of the proper type of electrode is necessary. Table 12-1 gives recommended applications for the main types of electrode for welding plain-carbon steel as classified by the AWS:

Table 12-1. Types of Electrodes

AWS classification	For deep penetration	For poor fit-up	For finish pass on deep-groove welding	For ease of operation in all positions	For steels with tendency for		
					Weld cracks	Internal porosity	Surface holes
E6010	x					x	
E6011	x					x	
E6012		x			x		x
E6013		x			x		x
E6013		x		x			
E6030	x					x	
E6020	x		x			x	

The largest electrode possible consistent with normal ease of operation should be used. This permits the use of higher currents.

2. Proper attention should be given to securing good fit-up in the parts being welded. Poor fit-up requires extra care and time to secure a satisfactory weld. The slower speeds also mean that more heat is being concentrated on the work which tends to increase problems of distortion.

3. The operator should always try to weld in the down-hand position with the joint level wherever possible. Speeds can be increased by as much as 400 per cent by changing from vertical to down-hand welding. Furthermore, considerably less skill is required to put *down* a good weld than is required to put *up* a good weld.

4. Excessive corrosion, paint, or other foreign matter should be removed from the edges to be joined.

5. Excessive build-up of weld metal should be avoided as wasteful. Only the specified amount of metal needed for strength should be deposited.

While all the above recommendations are for welding on mild steel, they should become the basis for the further development of all welding procedures. They are the fundamentals of good welding.

Illustrated in Fig. 12-6 are welds as they appear when made under various controlled conditions.

Location of Welds. The location of the welds in relation to the parts joined, in many cases, has an effect on the strength of the welded joint. As an example, repeated tests reveal that, when other factors are equal, welds having their linear dimension transverse to the lines of stress are stronger per average unit length than welds with linear dimension parallel to lines of stress. This is due to the stress distribution along the bead (Fig. 12-7*A*).

If the load on the weld is to be properly distributed, the welds should be located so as to take account of the shape of the sections joined. The ratio of the lengths of the welds at heel and toe of the angle (Fig. 12-7*B*) is such that there will be no tendency for the angle to turn and thus cause eccentric loads on the joint.

Resistance to a turning effect of one member at a joint is best obtained by welds well separated rather than by a single weld or welds close together. (Fig. 12-7*C*. A single weld at *A* is not so effective as welds at both *A* and *B*.)

If possible, welded joints should be designed so that bending or prying action is minimized. Symmetrical joints are most desirable as they are very much stronger than nonsymmetrical joints, the stress in symmetrical joints being more evenly distributed.

In some designs it may be desirable to take into account the distribution of stress through the welds in a joint. It is known that any abrupt change in surface (*e.g.*, a notch or saw cut in a square bar under tension) increases the local stress or causes stress concentration. In many cases such concentration of stress might be small and of minor consequence. However, in heavy or repeated loadings, this matter should have the attention of the designer (Figs. 12-7*D*, *E*, and *F*).

Stress in a weld having its linear dimension approximately parallel to the line of force is not evenly distributed. Under many load conditions, not at all unusual, the stress is greater at the ends of the weld than in the middle. It is therefore advisable in certain conditions to hook the bead around the joint. When this is done, far greater resistance to a tearing action on the weld is obtained (Fig. 12-7*G*).

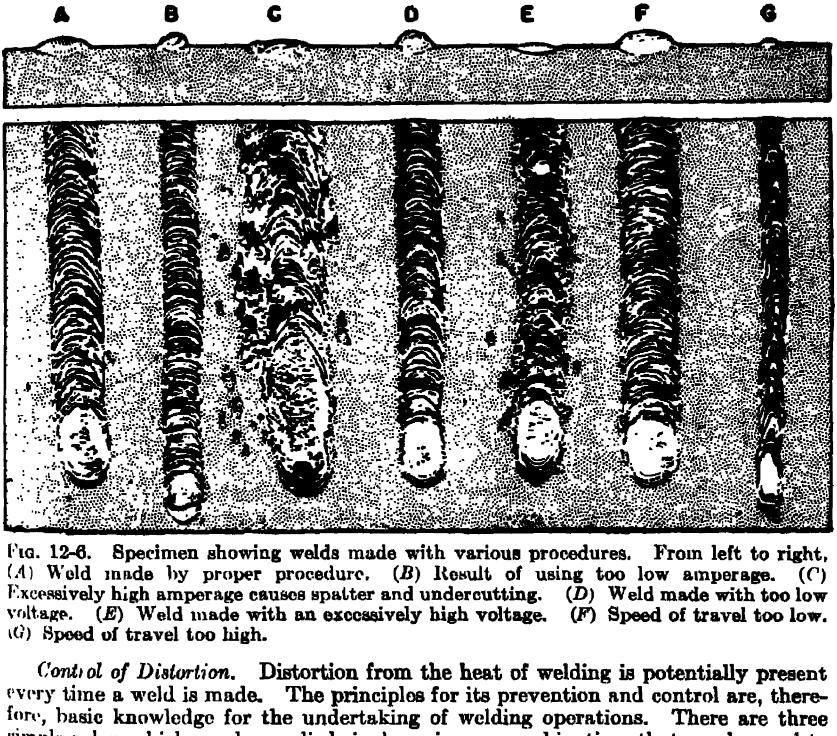

Fig. 12-6. Specimen showing welds made with various procedures. From left to right, (*A*) Weld made by proper procedure. (*B*) Result of using too low amperage. (*C*) Excessively high amperage causes spatter and undercutting. (*D*) Weld made with too low voltage. (*E*) Weld made with an excessively high voltage. (*F*) Speed of travel too low. (*G*) Speed of travel too high.

Control of Distortion. Distortion from the heat of welding is potentially present every time a weld is made. The principles for its prevention and control are, therefore, basic knowledge for the undertaking of welding operations. There are three simple rules, which can be applied singly or in any combination, that can be used to prevent and control distortion:

1. Reduce the effective shrinkage force. This can be accomplished in a number of ways:

a. Avoid overwelding. Addition of excess weld metal—not needed to meet the service requirements of the joint—is known as overwelding. This causes distortion and contributes nothing to the strength and performance of the joint. Weld metal should be kept at a minimum.

Another way of stating this principle is as follows: Use as little weld metal as possible, and make an intelligent use of the weld metal that is needed. For a conventional fillet weld for a T joint, it is known that the strength is determined by the effective throat (see Fig. 12-8). There is an excess of weld metal above the line *AA*, which does not increase the strength but obviously increases the effective shrinkage force. Less shrinkage force may be obtained with no loss of strength by using the deep-fillet technique. In contrast to the conventional weld, the deep penetration at

Fig. 12-7. Effect of location and type of weld on strength of joint: (*A*) Transverse welds are stronger than welds parallel to lines of stress. (*B*) Example of correct lengths of welds for equal load distribution (*C*) Example of proper placement of welds to resist turning effect of one member at joint. (*D*) Example of lap weld having poor distribution of stress through weld. (*E*) Example of lap weld having a more even distribution of stress through weld. (*F*) Example of lap weld in which there is fairly uniform transfer of stress through weld. (*G*) Example of welds hooked around the corners to obtain resistance to tearing action under eccentric loads.

the root of the fillet, using the deep-fillet method, gives 15 per cent more strength with the use of 30 per cent less deposited metal. Less weld metal means less distortion (see Fig 12-9).

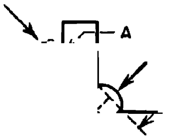

Fig. 12-8. Conventional fillet weld for T joint.

b. Use proper edge preparation and fit-up. It also is possible to reduce the effective shrinkage force through proper edge preparation. To obtain the proper fusion at the root of the weld with a minimum of weld metal, the bevel should not exceed 30 deg. Proper fit-up also is important, so the plates to be welded should be spaced $\frac{1}{32}$ to $\frac{1}{16}$ in. apart. A minimum amount of weld metal then will be needed to produce a strong joint.

c. Use few passes, which is another way to make an intelligent use of weld metal. Distortion in the lateral direction always is a major problem. Use of one or two passes with large electrodes reduces distortion in this direction. In general, lateral distortion is approximately 1 deg per pass.

In some cases, however, distortion in the longitudinal direction is a problem, and then, owing to the greater ability of a small bead to stretch longitudinally (compared to a large bead), the number of passes should be increased rather than decreased. This apparently paradoxical relationship is a function of the thickness of the plate and its natural resistance to distortion. There is inherent rigidity against the longitudinal bending of a plate provided the plate is thick enough. Light-gauge sheets have little rigidity in this direction and therefore will buckle easily. Unless the two plates to be

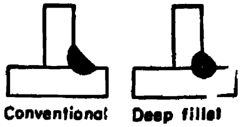

Fig. 12-9. Reduction of weld metal used through deep-fillet technique.

welded are restrained, there is no lateral rigidity whatsoever, since each of the two plates is free to move angularly with relation to one another, so lateral distortion is more common.

d. Place welds near the neutral axis. Another means of reducing the effective shrinkage force is to place the weld as close as possible to the neutral axis. In a conventional fillet weld, for example, the weld is so far from the neutral axis that it has sufficient leverage to pull the plates out of alignment. Use of the deep-fillet method places the weld close to the neutral axis which reduces the leverage (Fig. 12-10).

e. Use intermittent welds. To further reduce effective shrinkage force by minimizing the amount of weld metal, intermittent welds may be used in many cases instead of continuous welds. Often, it is possible to use up to two-thirds less weld metal and still obtain the strength required. EXAMPLE: Stiffeners for bulkheads and plates of all kinds. The use of intermittent welds also distributes the heat more widely throughout the structure.

f. Use "backstep" welding method. If the job requires a continuous weld, it still is possible to reduce the effective shrinkage force by the backstep technique. With this technique, the general direction of welding progression is, say, from left to right, but each bead is deposited from right to left (see Fig. 12-11).

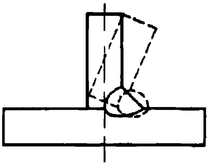

FIG. 12-10. Reduction of leverage by placing weld close to neutral axis with deep-fillet method.

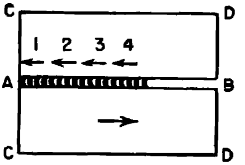

FIG. 12-11. "Backstep" technique of welding.

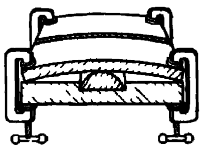

FIG. 12-12. Prebending before welding to exert counterforce against shrinkage force.

As each bead is applied, the heat from the weld along the edges causes expansion there which temporarily separates the plates at end *B*, but as the heat moves out across the plate to *C*, the expansion along the outer edges *CD* brings the plate back together. This occurs when the first bead is laid. The same will be true with each successive bead as it is laid, the plates expanding to a less and less degree with each bead because of the locking effect of each weld.

Where a continuous bead is laid in one direction, in many cases there is a tendency for the plates to spread and become locked in the spread position as the welding progresses. However, welding speed is the determining factor here. As a general rule, the greater the speed, the more the amount of spreading. In some cases a speed can be found at which the plates will not separate at all, and a slow speed may close the plates. This action is independent of current values for a given joint, being solely a function of the speed of travel of the arc.

2. Make shrinkage forces work to minimize distortion.

a. Locate parts out of position. A simple way to use the shrinkage force of weld metal to advantage is to obtain proper location of parts before welding. For example, a T weld may be made with the vertical plates out of alignment before the weld is deposited. When the weld shrinks, it will pull the vertical plate to its correct 90-deg position.

b. Space parts to allow for shrinkage. Another method is to space parts before welding. Experience indicates just how much space should be allowed for any given job, so that the parts will be in correct alignment after welding is completed.

c. Prebend. Shrinkage force can be put to work in many cases by prebending or prespringing the parts to be welded. For example, when the plates in Fig. 12-12 are sprung away from the weld side, the counterforce exerted by the clamps overcomes most of the shrinkage tendency of the weld metal, causing it to yield. But when the clamps are removed, there still is a slight tendency for the weld to contract, and this contraction of shrinkage force pulls the plates into exact alignment.

3. Balance shrinkage forces with other forces. Often the structural nature of parts to be welded in such as to provide sufficient rigid balancing forces to offset welding shrinkage forces. This is particularly true in heavy sections where there is inherent rigidity because of the arrangement of the parts. If, however, these natural balancing forces are not present, it is necessary to balance the shrinkage forces in the weld metal in order to prevent distortion.

a. Balance one shrinkage force with another. This can be accomplished by the use of proper welding sequence which places weld metal at different points about the structure so that, as one section of weld metal shrinks, it will counteract the shrinkage forces of previous welds already made. A simple example of this is welding alternately on both sides of the neutral axis in making a simple butt weld (see Fig. 12-13).

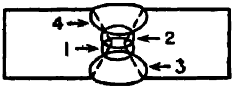

FIG. 12-13. Welding sequence to balance one shrinkage force with another.

Another application of this principle is the staggering of intermittent welds applied in a sequence. Here the shrinkage force of weld 1 is balanced by that of weld 2; the shrinkage force of weld 2 is balanced by that of weld 3, etc.

b. Peening. By peening the bead, it actually is stretched, counteracting its tendency to contract and shrink as it cools. Peening should be used with great care, for too much peening may damage the weld metal.

c. Use jigs and fixtures. The most important method of avoiding distortion, and one in which rule 3 is applied to the fullest extent, is the use of clamps, jigs, or fixtures to hold the work in a rigid position during welding. In this way, the shrinkage forces of the weld are balanced with sufficient counterforces to prevent distortion. What actually happens is that the balancing forces of the jig or fixture cause the weld metal itself to stretch, thus preventing the distortion.

WELDABILITY OF METALS

This discussion has been confined largely to the welding of mild steel. The fundamentals for welding mild steel are the basis for the development of procedures for the welding of special alloys and the other nonferrous metals. By applying certain cautions and special techniques, practically all metals have been successfully arc-welded.

Following is a brief description of the general principles involved in determining the weldability of metals and in establishing procedures. Space does not permit a complete detailed description of the many varied techniques. Electrode manufacturers provide complete procedure information for all their special electrodes.

Obviously some metals will weld more readily than others. The economy and quality of the welding on various metals may be affected by any one of the following factors:

1. Oxidation. (*a*) Oxidation producing a gaseous oxide of some one of the elements causing gas holes in the weld metal; (*b*) oxidation producing solid oxides which have a melting temperature higher than the metal, thus causing slag inclusions, (*c*) oxidation producing oxides which are soluble or which are heavier and sink in the molten metal and which render the weld metal brittle or of low strength.

2. Vaporization. Vaporization of some element in the metal which vaporizes at a temperature lower than the melting point of the metal.

3. Nonmetallic Inclusions. Some metals may contain finely divided nonmetallic inclusions which have a melting point higher than that of the metal and therefore did not coalesce when the metal was refined but do melt and coalesce under the high temperature of the arc and then form visible slag inclusions.

4. Change of Structure. Change of structure or arrangement of elements within the metal may take place during arc welding, causing change of physical properties or change of resistance to corrosion, etc.

5. Gas Solubility of Metal. (*a*) Different elements may affect the solubility of various gases at different temperatures, and a decrease in solubility of a gas with a decrease in temperature at the freezing point may cause porosity in weld metal. (*b*)

The fluxing out or elimination of an element during welding may cause the capacity of the metal for a given gas to decrease and thus cause the gas to be given up producing porosity in the weld metal. (*c*) Absorption of gases during welding which form stable compounds with elements in the metal and thus alter the composition and physical properties of the weld metal.

6. **High Coefficient of Thermal Expansion,** or high contraction of weld metal upon cooling.
7. **"Hot Shortness,"** or low strength of the metal at high temperatures.
8. **Thermal Conductivity,** or rate of transfer of heat from fusion zone.

The above outline indicates why some metals are more satisfactory than others.

A careful study of these factors indicates that most of the possible undesirable characteristics can be corrected by one or more of the following methods:

1. Selection of metal within the permissible class most suitable for arc welding
2. Use of a properly shielded arc
3. Use of proper fluxing material
4. Use of proper electrode or filler metal
5. Proper welding procedure
6. Subsequent heat-treatment which may be required in some cases

In considering the weldability of any metal it should be realized that the weld largely depends upon the characteristics of the weld metal which may come from two sources, *viz*, base metal and electrode of filler metal.

If little or no electrode or filler metal is used, the proper selection of the base metal becomes of prime importance. If the weld metal comes mostly from the electrode or filler metal, the selection of the proper electrode or filler metal becomes of prime importance. However, both electrode and base metal are subjected to similar requirements during arc welding, and both should be of best arc-welding quality, although in many cases the electrode or filler metal serves as a corrective for the base metal.

The carbon content of steel is the most important factor in determining heat-treatment procedures. When the carbon content is low, the weldment will require no special consideration. When it is high, preheating is generally necessary at a temperature usually from 450 to 650°F in order to control the rate of cooling.

Failure to preheat high-carbon steel before welding on it will usually result in the hardening of the steel adjacent to the weld. Since this will reduce the ductility of the steel, cracking in the metal next to the fusion zone is likely to result. This steel should be welded while it is hot and then allowed to cool slowly, increasing the cooling time proportionately as the carbon content of the steel is greater. For steel above 40 per cent carbon, overnight cooling in a furnace is sometimes necessary to avoid a hardened zone. Type E6015, E6016, E7015, and E7016 electrodes are recommended for welding high-carbon steels, although the normal mild-steel electrodes can be used.

Definite limitations and specifications for preheating should be established only after experience. Research is discovering that preheating is unnecessary in many applications where it is generally thought to be desirable. The service requirements of the weldment must be considered as well as the use of welding procedures to control the forces created by the heat (see Control of Distortion).

SURFACING BY ARC WELDING

The use of arc welding to deposit a surface of metal of a desired characteristic has many applications in plant operation: building up worn shafts, lining carbon-steel vessels with stainless steel, and the application of wear-resisting surfaces to machinery of all kinds.

The success of the application of surfacing metal by welding depends largely on the choice of the proper surfacing material which in turn is dependent on the following factors:

1. Material to be surfaced
    a. Its composition
    b. Its physical condition, such as hardness, previous heat-treatment, etc.

2. Dimensions
    a. Size and shape of parts
    b. Size and location of the area to be surfaced
    c. Thickness of weld deposit
3. Finish required
    a. As welded
    b. Machined
    c. Rough grind
    d. Fine grind
4. Service conditions
    a. Hardness required
    b. Corrosion, the corrosive medium
    c. Abrasion, its extent and nature
    d. Impact, its extent and nature

Materials to Be Surfaced. The hundreds of metal alloys can be grouped for consideration of their suitability to weld surfacing into two general groups:

In group A are metals or alloys whose physical characteristics are not greatly changed as a result of heating and cooling and which will withstand sudden localized temperature changes without cracking. This group includes plain-carbon steel with 0.30 carbon maximum, low-carbon alloy steels, austenitic steels such as the stainless chrome-nickel, and the high-manganese steels. Copper and most of its alloys would also be included.

In group B are those material or alloys whose physical characteristics are changed considerably (particularly as to hardness) as a result of the application of welding heat and subsequent cooling or which will crack with the sudden application of localized heat. This group includes medium- to high-carbon steels, tool steels, medium- to high-carbon low-alloy ferritic steels, cast irons, and, in general, all hard metals and alloys.

The metals in group A can be weld-surfaced without any particular precautions such as preheating since the thermal cycle incident to the welding will not cause harmful cracking or hardening.

Special precautions must be exercised in weld surfacing metals of group B to avoid cracking due to thermal shock. Either the hardness of the metal must be reduced through annealing or the thermal shock reduced by preheating. In some cases both may be necessary.

Further precaution is necessary in group B to minimize weld hardening. Metal adjacent to the weld will harden when cooled quickly following heating to temperatures high enough to cause solution of free carbides. This may result in subsequent cracking, failure of the part, or spalling of the weld deposit. To reduce the tendency to weld-harden, preheating, slow cooling, and postheating, or a combination of these, may be employed.

Dimensions. The size and shape of parts determine largely the heat capacity of parts to be surfaced and therefore determine to some extent the thermal cycle to which the part and the weld deposit are subjected. A large mass and large heat capacity will heat up slowly, reach a relatively low temperature, and draw the heat away from the weld area rapidly. A small mass will heat up rapidly, reach a high temperature, and draw the heat away from the weld area slowly. If local welding heat is applied to a large mass of metal, which is capable of being quench-hardened, the hardening will be drastic and cracking is likely to result due to thermal stresses. If the mass is small, the degree of hardening will be less because of its low heat capacity and cooling will be more uniform throughout, resulting in less severe thermal stresses. If the weld metal being deposited is of the type whose hardness is affected by the thermal cycle, the hardness of the deposit will be greater on a large mass owing to the quench effect.

Heat input will also be determined by the size and location of the area to be surfaced. The size of the area will, therefore, influence the thermal cycle as the size and shape of the part itself does.

Finish Required and Service Conditions. Electrodes for hard surfacing are not well adapted for vertical or overhead welding. Work should be placed in as nearly flat a position as possible. Thick deposits should be generally avoided. If thick deposits are desired, electrodes designed for such applications must be used. If machining is to be done on the deposit, it must be necessary to anneal. In some cases grinding is the only way to work the deposits.

In all cases, for the best results in hard surfacing, manufacturers' recommendations for the use of their electrodes should be studied and followed.

The various service conditions to which a weld-faced deposit may be subjected can be classified as follows:

1. *Abrasion.* (*a*) Abrasion is a grinding action due to rubbing against an abrasive material such as rock, sand, clay, or soil or due to (*b*) sliding, rolling, or rubbing action of one metal part against another. Either *a* or *b* may take place under high or low pressure.

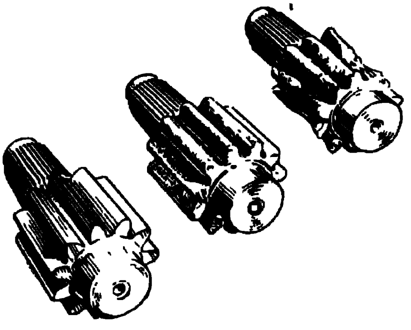

Fig. 12-14. Parts reclaimed through hard surfacing with arc welding. Badly worn pinion gears can be built up and ground to shape and made as good as new. Gear at left is ready for use.

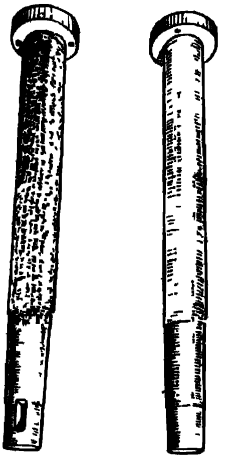

Fig. 12-15. Grinding-machine journal shaft rebuilt by electric welding. Shafts were first machined, $\frac{1}{32}$ in. being taken off the radius to remove worn spots, then built with application of abrasion-resistant weld metal. The entire job required 5 hr.

2. *Impact.* Impact takes place in various degrees from light to heavy. It tends to deform the surface or cause cracking or chipping.

3. *Corrosion.* Corrosion includes the action of various chemicals, ordinary water, and also oxidation or scaling at elevated temperatures.

It is obvious that, before the proper choice of weld-surfacing material can be made for a given application, the service conditions must be analyzed. In cases where more than one of the wearing factors are at work, their relative importance must be determined.

For determining the economy of weld surfacing, see Table 12-2. Surfacing metal is expensive, and by depositing only a limited quantity of it on a low-cost base metal, instead of making the part completely of the expensive metal, great savings can be made in both reclaiming worn equipment and building new machinery or tools (see Figs. 12-14 and 12-15).

Table 12-2 indicates that, for a surface material as high in cost as $5 per lb against an original cost of 20 cents per lb, 3 per cent may be surfaced by welding and the original cost not exceeded. More usually it will be found that 20 per cent or more may be surface metal without exceeding the original cost.

Table 12-2

Cost cents/lb, using single metal	Percentage of total weight which may be surface material without exceeding cost of using one metal throughout				
	Cost of surface materials				
	$1/lb	$2/lb	$3/lb	$4/lb	$5/lb
20	15.8	7.7	5.1	3.8	3.0
40	37.0	18.0	11.9	8.9	7.1

100	100.0	48.7	32.2	24.0	19.2
120		59.0	39.0	29.1	23.2
140		69.2	45.7	34.2	27.3

SHEET-METAL WELDING

The welding of sheet metal has frequent application in plant operation (Figs. 12-16 to 12-19). The same principles of good welding practice as previously outlined apply in welding sheet metal, but the nature of the work places special emphasis on several aspects. The problem of distortion requires special consideration in welding thin-gauge metals as well as the problems of burning through the metal.

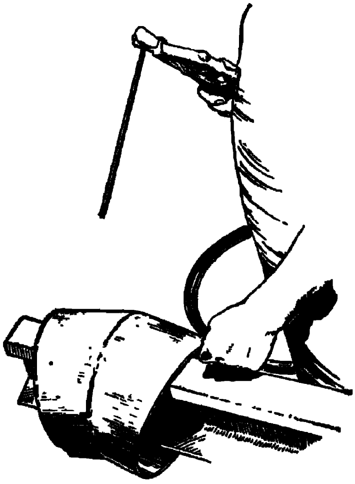

Fig. 12-16. Welded fabrication simplifies making of angles for piping in ventilating systems. Filing or grinding of the metal may be necessary to secure a fit-up that will result in airtight joints and the required angle. The angle illustrated is made of 11-gauge galvanized steel.

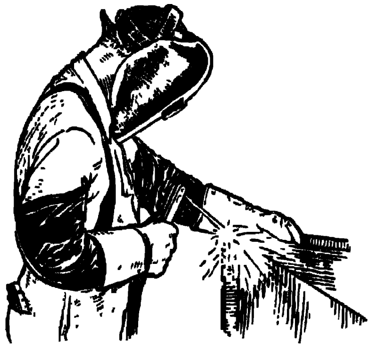

Fig. 12-17. Section of an air duct being welded out of 18-gauge galvanized iron Corner joints are tacked every 2 in., then welded with a ⅛-in. electrode at a 45-deg angle.

Special attention should therefore be given to all the factors involved in controlling distortion: the speed of welding, the choice of proper joints, good fit-up, position, selection of proper current, use of clamping devices and fixtures, number of passes, and sequence of beads.

Within the limits of good welding appearance, the highest arc speeds and the highest currents should be used. In sheet-metal work, however, there is always the

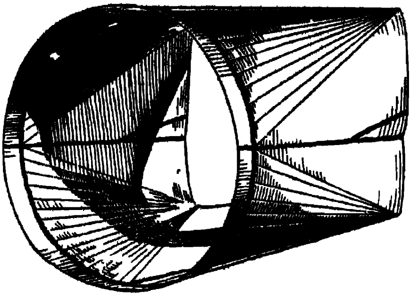

FIG. 12-18. Exhaust stack made of 14-gauge 18-8 stainless steel. All joints are butt-welded with a 1/8-in.-diameter electrode.

Table 12-3. Sizes of Electrodes for Sheet Metal

limitation imposed by the threat of burn-through. As the gap in the work increases in size, the current must be decreased to prevent burn-through which of course will reduce welding speeds. A clamping fixture will improve the fit-up of joints and thus make possible the higher speeds. If equipped with a copper backing strip, the clamping fixture will make for easier welding by decreasing the tendency to burn through, and will also remove some of the heat which causes warpage. Sheet-metal joints, where possible, should be welded downhill at about a 45-deg angle with the same or slightly higher currents as are used in the flat position.

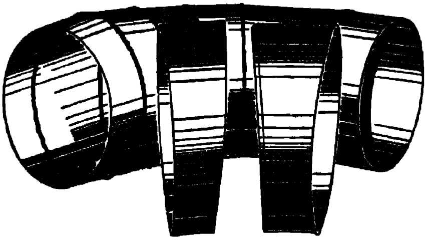

FIG. 12-19. Technique of welded elbows. Sections are butt-welded into rings, and edges are drawn with hammer and dolly.

Tables 12-3, 12-4, and 12-5 offer a guide to the selection of the proper size electrode, current, and voltage for the various types of joints as used with sheet metal ranging from 20 to 8 gauge.

STRUCTURAL WELDING

Extreme simplicity is a fundamental advantage of arc-welded design in structures. Arc welding joins two members directly to each other without the use of a third or connecting member (Fig. 12-20). While this simplicity is responsible for savings in designing, detailing, and erecting, nevertheless stresses at all connections must be calculated and the required weld specified.

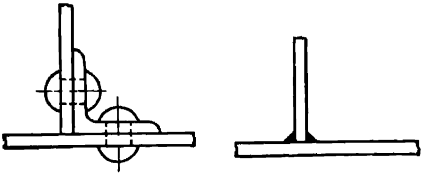

FIG. 12-20. Simplicity of welded design.

Table 12-6. Length of Fillet Weld to Replace Rivets
(Larger value in each case for emergency allowable)

Rivet diam, in.	Rivet shear value @ 15,000 psi*	Length of fillet welds (to nearest ⅛ in.), "fusion code" (structural),* shielded arc welding				
		¼-in. fillet, in.	5/16-in. fillet, in.	⅜-in. fillet, in.	½-in. fillet, in	⅝-in. fillet, in.
½	2,950	1½	1¼	1⅛	⅞	¾
⅝	4,600	2¼	1¾	1½	1¼	1

⅞	9,020	4⅛	3⅜	2⅞	2⅛	1¾
1	11,780	5¼	4¼	3⅝	2¾	2¼

* AISC value for rivet in shear is 15,000 psi, for weld in shear it is 13,000 psi (American Institute of Steel Construction).

NOTE: ¼ in. is added to calculated length of fillet.

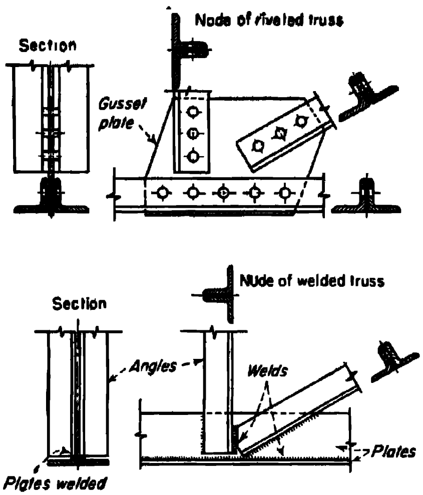

FIG. 12-21. Node of riveted and welded trusses showing how welded design cuts dead weight and reduces secondary stresses for greater factor of safety.

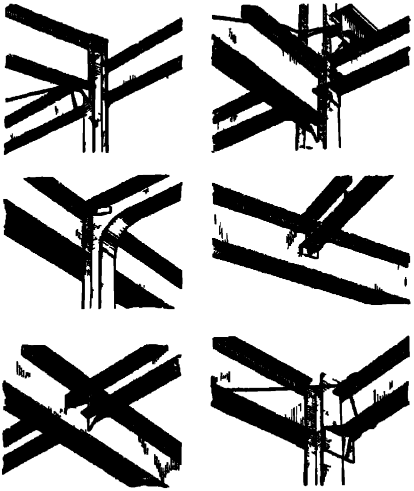

FIG. 12-22. Examples of facilities provided in steel erection by use of welding are the various clip angle seats, split I-beam segments, tie-rod clips, etc., which are shown. (*Top left*) Junction of roof beam and eaves strut at front, (*top right*) typical connection of girder and beam to column, (*center left*) junction of roof beam and eaves strut at rear; (*center right*) junction of roof beam and girder; (*bottom left*) junction of lower roof beam at girder; (*bottom right*) intersection of lower roof beam and girder.

The chief economy is less material. Trusses properly designed for arc welding require practically no gusset plates (Fig. 12-21). An entire structure fabricated by arc welding acts as a single member, and therefore lighter members usually can be used. Savings in material on structures have run generally between 15 and 25 per cent.

Welding also reduces the handling of material in fabrication. Welded connections require only two operations and only a welding machine for equipment. Much of the handling of the main members is therefore completely eliminated.

Welding permits the designer to place material in the structure where it is needed to meet the load demands without being restricted by considerations for the fabricating process. This simplification makes practical the construction of rigid frame structures with their freeing of internal space from supporting columns.

A detailed discussion of the design considerations in welded columns, beams, girders, trusses, bracing, bar joists, and rigid frame construction is not possible here but should be investigated before undertaking welded structural work of any kind. Figures 12-22, 12-23, and 12-24 indicate some of the possibilities (see Table 12-6 for the necessary length of fillet weld to replace rivets).

PIPING

Piping systems welded in shop and field have been installed in buildings, plants, offices, powerhouses, and ships. The advantages of arc-welded piping include permanently tight connections of greater strength and rigidity, less resistance to flow owing to elimination of projections inside the pipe, more pleasing appearance, easier and cheaper application of insulation, simplification of design, and the elimination of many fittings.

Table 12-7

Size of pipe		Beads or passes	Electrode size in	Current, amp	Arc time min/joint	Pounds of electrode/joint

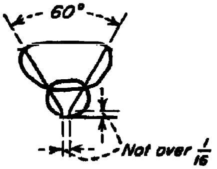
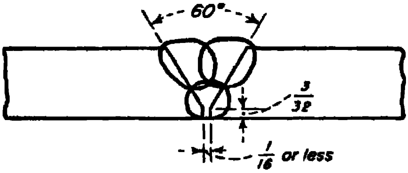
14‡	0.375	1 2 3 4	3/16	150 170	31.3	2.3

* See Fig. a

† See Fig. b

‡ See Fig. c.





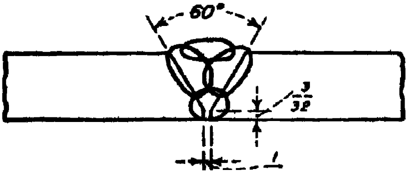


Table 12-7 and Figs. *A*, *B*, and *C* contain procedure data, speeds, and amount of electrode required for welding butt joints in standard-weight pipe in horizontal position.

Pipe above 12 in. in diameter may be obtained in a great many different wall thicknesses. Inasmuch as pipe is being used in these larger diameters for h-p and high-temperature service, the data in Table 12-8 are suggested for use in determining the number of passes to be used for the various pipe thicknesses:

Table 12-8

Pipe thickness	*Number of passe*
¼	3-4
⅜	4-5
½	6-8
¾	11-14
	13 16

The electrode size will be $\frac{5}{32}$ and $\frac{3}{16}$ in., depending upon the particular design, the load conditions, and the specifications. For example, on 14-in. pipe, $\frac{3}{16}$-in. electrode is normally used for passes; whereas in case of very h-p work, a $\frac{5}{32}$-in. electrode is used for the first pass, and $\frac{3}{16}$ in. for the following passes.

Piping for h-p and high-temperature systems has been increased in efficiency by the use of welded design. Welded joints permit high operating stresses and thinner sections. However, these systems must be designed according to code, giving due consideration to stress distribution, and for all unusual conditions of loading.

In the field work of installing a welded piping system, a method must be worked out for the inexpensive and quick laying out of the various types of joints. There are several methods which may be used. One that is simple and can be used in almost all cases is the use of fixture with movable fingers which will give the desired contour merely by holding it against the pipe in the necessary position. Another method is to use templates, giving the operator the exact curve, which can be fitted around the pipe's circumference to indicate the precise cutting curve The third method is the use of special curves on a master drawing. The only equipment needed is the master drawing, a string, a piece of chalk, and a scale.

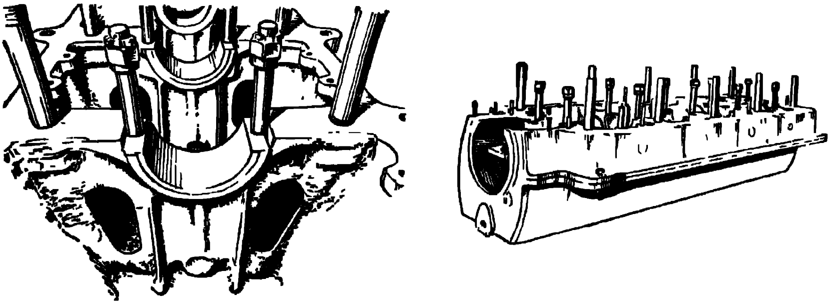

FIG. 12-25. Welded repair of a diesel-engine base. Studding was used together with an electrode of the mild-steel type.

TANKS AND PRESSURE VESSELS

Arc welding can be used to fulfill all the requirements imposed by the operating conditions of all types of tanks. Pressure, temperature, and chemical reaction are withstood without leakage under all load conditions.

A properly designed and welded joint is 20 to 30 per cent stronger than the plate itself. Plate thickness, therefore, need not be so great, and all punching and caulking operations are unnecessary. Maintenance costs are practically negligible as the joints are permanently tight and have greater resistance to corrosion.

Pressure vessels should be built in accordance with the ASME Boiler Code which requires definite procedure of welding and stress relieving. Butt joints are used entirely in this class of work. Plate thicknesses generally range from 1 to 3 in., and practically all the welding is done by the shielded arc process.

MISCELLANEOUS REPAIRS

In addition to the various types of work that have been classified in the foregoing sections, the repair or replacement of broken parts of all types of machinery is greatly

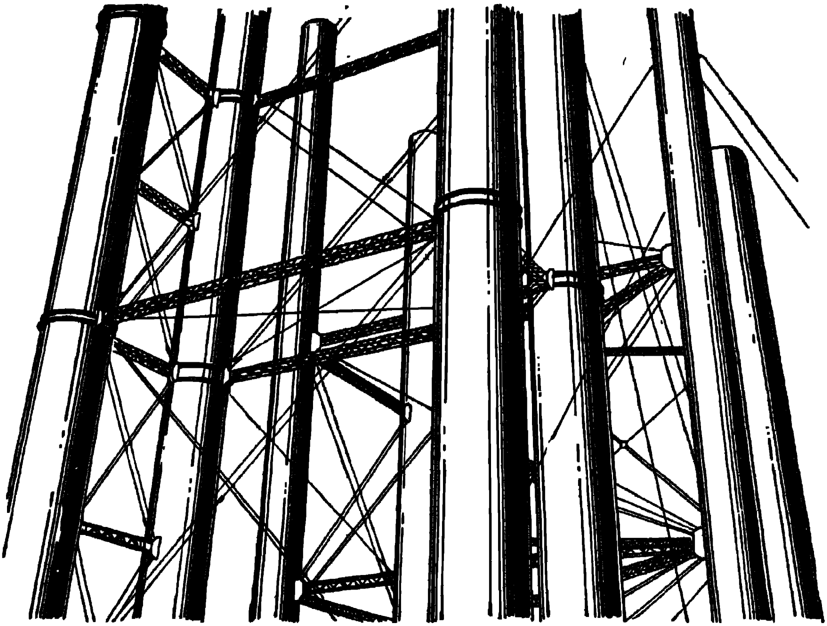

FIG. 12-26. Restoring rusted smokestacks by welding on ¼-in. plate rolled to circumscribe the stack. Plates were beveled to 60 deg and welded in two passes.

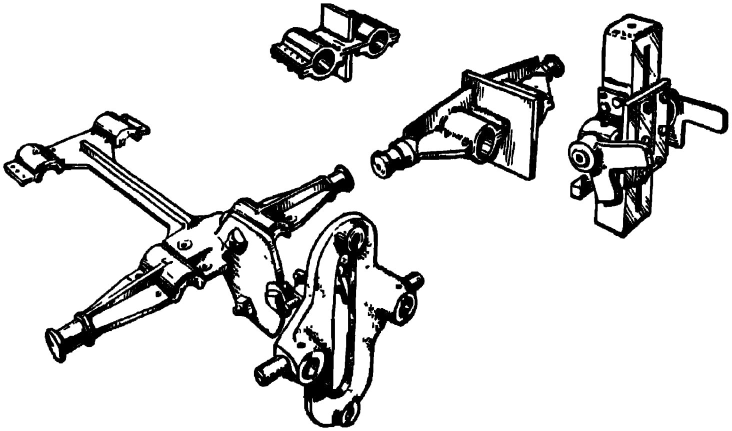

FIG. 12-27. Welded steel parts (right) to replace broken castings (left) from a 20-year-old dragsaw.

facilitated through the use of arc welding. The procedures used will vary with the nature of the job, and no attempt can be made to outline the many possibilities. When the repair is made without dismantling the machine, naturally compromises in procedure have to be made to meet the conditions. Sound welding practice should be the guide in all cases.

Figures 12-25, 12-26, and 12-27 are typical examples of repairs or replacements that were effected through the use of arc welding.

SILVER-ALLOY BRAZING

BY C. H. CHATFIELD

Senior Metallurgist, Handy and Harman, Bridgeport, Connecticut

AND J. L. CHRISTIE

Metallurgical Manager, Handy and Harman, Bridgeport, Connecticut

INTRODUCTION

Brazing is a process of joining metals by means of heat, wherein a nonferrous filler metal having a melting point lower than those of the metals or alloys being joined is used. To differentiate brazing from soft soldering, an arbitrary minimum temperature of 800°F for the melting point of a brazing alloy has been quite generally accepted. The present trend is to classify brazing as a welding process, although the common concept of a weld has been that of a joint made by actual fusion of the base metals being joined. Distinguishing features of a braze are that a filler metal is always used and that this filler metal always melts below the melting point of the base metals. The metals being joined are never heated to the point of fusion. Another feature of a braze is that the surfaces of the joint are fitted closely enough to permit the flow of the brazing alloy through the joint by capillarity.

Brazing is an extremely old process of joining metals. It is probable that it was originally called "brassing" because of the fact that the first brazing alloys were brass. These brass alloys contained copper and zinc in about equal parts and melted at approximately 1600 to 1650°F. Because of their high zinc content, they were also called spelter solders. Many years ago it was discovered that the addition of silver to the brass alloys lowered the melting points of the brass and produced alloys having increased ductility which could be fabricated into sheet and wire—forms which were more convenient to use than the usual granulated form of the spelter solders. These new alloys were called "silver solders" or "hard solders." In recent years the silver alloys have been quite generally called "silver brazing alloys" in order to avoid any confusion with the tin-lead alloys and similar soft solders, as the properties of joints made with the silver brazing alloys bear closer resemblance to joints made with the brass alloys than to joints made with soft solders.

The silver brazing alloys are composed chiefly of silver, copper, and zinc, but other metals, such as cadmium, tin, manganese, and nickel may be added to impart specific properties. The melting points of the alloys will vary from approximately 1150 to 1600°F depending upon the composition. Other silver alloys are available with melting points both above and below this temperature, but they have not been used to any great extent commercially. It is these relatively low melting points of the silver alloys as compared to brass alloys, combined with high joint strengths obtainable with a corresponding minimum loss in strength or other desirable properties of the base metals being joined, which has been an important factor in their wide acceptance for industrial applications.

Because of their malleability, silver brazing alloys can be obtained in various shapes and sizes. Sheet can be obtained in all gauges down to 0.003 in. and can be used for inserts in joints when making lap or scarf joints. Washers can be made from sheet and used as inserts for joining flanges or spuds to tanks. Strips of various widths are used for hand feeding or can be formed into rings for use as inserts.

Wire is also available and is convenient and economical for use in hand feeding or forming into rings for preplacing.

Silver brazing alloys in the form of filings or powder in sizes from 20 to 150 mesh can also be obtained. This form is useful when it is more convenient to sprinkle the alloy on the joint before heating. Because of the large surface area of the alloy in this form, particular care must be taken to protect the alloy with flux to prevent oxidation.

USES

The current shortages of metals have given a strong impetus to the trend in industry to lighten, without loss of strength, equipment of all sorts. This has led to the building up of equipment from simple basic components which are readily fabricated by mass-production methods, thus eliminating the use of heavy, complicated castings or costly machining from a single piece with the production of excessive scrap. A natural consequence of this is the displacement of all types of mechanical joints wherever possible by the use of various welding processes.

As silver brazing alloys can be used for joining practically all ferrous and nonferrous metals and alloys except such low-melting materials as aluminum and zinc-base alloys, the use of silver brazing has expanded rapidly. The fact that silver brazing alloys are free flowing, corrosion resistant, and will produce strong joints makes them particularly suitable materials for accomplishing this objective.

A complete list of the uses of silver brazing alloys would cover practically every industry. They are used extensively in making airplane equipment for such things as cable tubes, gas and oil lines, instrument connections, radio shields, propeller connections, carburetor parts, and landing-gear parts. In the automotive industry they are used on flexible couplings, horns, gas and oil lines, spark plugs, steering wheels, vacuum gear-shift lines, and many other items. The dairy industry, where corrosion resistance and sanitary joints are important factors, uses silver brazing alloys. A recent development is the joining of pipe lines in radiant-heating systems where permanent leakproof joints are essential.

During the Second World War many vital parts of our fighting ships were joined with silver brazing alloys. Such things as deck fittings, electrical lines and switch boxes, oil lines, and pipe lines were brazed and successfully stood the test of battle conditions. In addition, brazed joints were used in most of the instruments aboard the ships.

Manufacturers of chemical equipment, tools, beverage dispensers, cooking utensils, sporting equipment, firearms, lawn mowers, bicycles, hardware, railroad equipment, and silverware all have applications where they use silver brazing. This list of users could be greatly expanded, but this will serve to show the wide field of commercial use of silver brazing.

The applications cited above deal with the fabrication of various types of equipment, but an important use of brazing which should not be overlooked is the repair and salvaging of broken parts. Examples are the repair of broken high-speed tools, such as broaches and milling cutters, without destroying the temper, retipping carbide tools, and the repair of broken shafts. Expensive equipment can frequently be reclaimed at a fraction of the replacement cost.

FUNDAMENTALS OF BRAZING

While silver brazing operations are relatively simple and unskilled workmen may obtain a high proficiency in a short training period, there are certain fundamentals which must be followed if the full advantages of the process are to be obtained.

The essential requirements for obtaining good joints may be divided into six general classifications, as follows:

1. Design
2. Preparation of joint surfaces
3. Fluxing
4. Assembling and jigging
5. Heating
6. Final cleaning

These requirements will be discussed individually.

Design. The three principal types of joints used in silver-alloy brazing are butt, scarf, and lap or shear, and each of them may be used with flat, round, or tubular members. Examples of these types, showing both good and poor design, are illustrated by Fig. 12-28.

Although not commonly used, except in those cases where lap- or shear-type joints cannot be accommodated by the shape of the parts to be joined, butt joints can be made which have remarkably high strengths. With the softer metals, such as copper or low-carbon steels, the strength of butt joints will often exceed the strength of the base metals; and even with many of the harder alloys the strength will customarily be higher than the elastic limit of the base metal. An excellent example of their strength is the use of butt brazes for the repair of broken broaches. The life of the repaired broach often is as long as that of a new tool. Another example would be hollow handles, where the two halves are stamped out of sheet and the edges of the stampings ground to give a close fit.

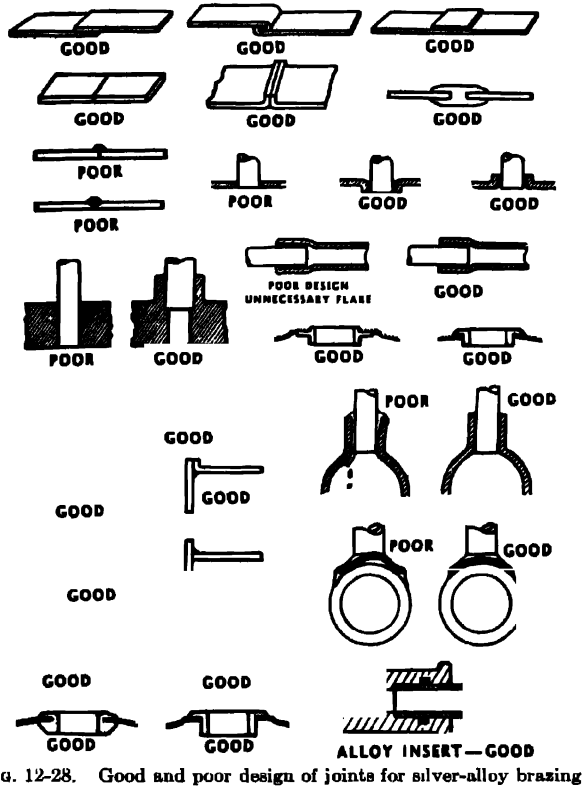

Fig. 12-28. Good and poor design of joints for silver-alloy brazing.

A scarf joint is a modified form of butt joint in which a larger bonded area is obtainable for the same thickness of metal. The strength of a scarf joint, however, does not increase proportionately to the increase in area when tested in tension. This is accounted for by the fact that such a joint fails by shear, and as the shear strength of a joint is lower than the tensile strength, the increase in area is to a great extent offset by the lower strength per square inch. A scarf joint does have an advantage in certain cases where it results in a different distribution of stresses than would be obtained in a butt joint. Typical uses for scarf joints are in joining band saws or heavy rod which is subsequently drawn to a smaller size.

Lap or shear joints are the most commonly used. They have the advantage that the bonding area can be varied to provide any desired factor of safety against breakage or leakage. The use of lap or shear joints frequently simplifies the problems of assembling and jigging, which is a distinct advantage where automatic brazing methods are used. Also, they lend themselves readily to the use of preplaced brazing alloy.

Where pressure can be applied to a lap joint, as in brazing sheet, tests have shown that, with such metals as copper, brass, or Everdur, strengths greater than that of the metal joined can be obtained with laps equal to the thickness of the sheet. With higher strength materials, such as monel or steel, this amount of lap is not sufficient. Also, with tubular members where pressure cannot be applied, as a rule, the strength of joint will not be so high as on sheet laps. In this case, a lap of about three times the thickness of the thinner member is recommended.

In order to obtain the maximum strength of joint, clearances of 0.001 to 0.003 in. are usually required. With less than 0.001 in. clearance, slight irregularities on the surface from file or machine marks may cause blocks where there are actual metal-to-metal contacts which will prevent flow of the brazing alloy. Too large clearances may break the capillarity through the joint and stop the flow of the brazing alloy.

The recommended clearances are made on the assumption that similar metals are being brazed and that the same clearance will be maintained when the joint is heated to brazing temperature. It is sometimes necessary with dissimilar metals to make allowances for differences in thermal expansion so that the desired clearances are obtained at the brazing temperature. For instance, in the case of a brass sleeve on a steel tube, the brass will expand more than the steel so that, to maintain a suitable clearance at brazing temperature, the clearance should be held on the minimum side or even to a drive fit when the parts are at room temperature. Conversely, if the brass fits inside the steel, the fit at room temperature should be looser, or else, when the parts are heated, the expansion may result in so tight a fit the brazing alloy cannot flow through.

The method of heating may also affect the clearance even though metals of similar thermal expansion are being joined. For example, in induction heating, the greatest heat is developed at the surface. If the heating coil is placed on the outside, the outer member will expand more than the inner member, and interference fits of as great as 0.005 in. are desirable. On the other hand, if the coil was placed inside the assembly, the reverse is true, and a clearance larger than normal would be necessary.

Preparation of Joint Surfaces. An important factor in getting good joints is to have the surfaces free from grease, oxide, scale, and dirt of any kind. Either chemical or mechanical methods may be employed.

Oil or grease is preferably removed by chemical means. There are many reliable cleaning compounds such as trichlorethylene, sodium phosphate, and others available for this purpose. Where only a few parts are to be cleaned, brushing the compound on will serve. If production warrants it, automatic machines for this purpose may be desirable. Emerying or other mechanical methods are not suitable means of removing oil or grease as they do not completely remove the film.

Oxides may be removed by a suitable pickle, the composition of the pickle depending upon the base metal. For copper or copper-base alloys a hot 10 per cent sulfuric acid pickle is usually satisfactory. Either dilute sulfuric or hydrochloric acid will work well on most steels. In some cases, such as nickel-base alloys or stainless steels, special pickles may be required. Directions for making and using such pickles can be obtained from the suppliers of the alloys.

Oxides or scale may also be readily removed by mechanical means. Filing, grinding, emerying, or sandblasting are commonly used. With sandblasting, care must be taken to wipe off any particles adhering to the surface as they will result in inclusions which will impair the strength of the joint. When filing is used, it should be a fine cut as deep scratches may cause trouble.

Deep scratches are to be avoided, for when the edges coincide on the two surfaces being joined, the fit may be too close to permit the free flow of the brazing alloy. Also, they may form channels through which the alloy will flow in preference to wetting the entire surface leaving excessive unbonded areas in the joint. On the other hand, a highly polished surface is also undesirable as the adherence of the brazing alloy is not so good as with a slightly roughened surface.

Parts should not be allowed to stand for extended periods of time after cleaning before brazing. Some metals build up oxide films on standing sufficient to interfere with the proper flow of the brazing alloy. In any case, dirt and other films may form on the joint surfaces.

Fluxing. With few exceptions, flux is required for silver brazing. Fluxes are used to prevent the oxidation of the brazing alloy and of the surfaces of the metals being joined during the heating. The flux will also dissolve oxides that may form during the heating operation.

The flux should be fluid, chemically active, and free from excessive fuming at the brazing temperature.

Borax and mixtures of borax and boric acid have been used as fluxes for silver brazing for many years. Borax does not have a definite melting point, but it is sufficiently fluid at 1400°F to make a good brazing flux. As the temperature drops below 1400°F, it gradually becomes more and more viscous. As the viscosity increases, the danger of entrapping flux in the joint also increases. The addition of boric acid increases the viscosity of the flux so that a 50 per cent borax and 50 per cent boric mixture is not fluid until a temperature of 1600°F is reached. Such a flux should be used only with the higher melting brazing alloys.

Borax is an excellent solvent for oxides. Boric acid is a poor solvent for oxides but because of its viscosity and imperviousness to air or other gases is a good flux for preventing oxidation. Fused borax left on the joint after brazing is relatively insoluble and therefore hard to remove. Fused boric acid is readily soluble in hot water, and mixtures of borax and boric acid are much more easily removed from the joint than borax alone.

With the development and extended use of brazing alloys melting below 1300°F, fluxes melting lower than borax were required in order to take full advantage of the lower brazing temperatures. Fluxes with a borate base but containing alkali fluorides have been developed which are fluid at temperatures above 1100°F, and they have largely displaced the older borax fluxes. The fluxes containing fluorides are particularly effective in dissolving refractory oxides, such as chromium oxides, and this has greatly broadened the use of silver brazing with stainless steel and alloy steels.

Special fluxes containing other halides are also available for difficult applications where the above fluxes are not satisfactory. A special flux is required, for instance, in brazing aluminum to steel.

Flux is usually used in a paste form thin enough so that it may be brushed over the surface. Brushing is preferable to other methods of application as the brushing tends to break down any films left on the surface from the cleaning operation to leave a thin, uniform coating over the entire surface. If the flux does not adhere readily to the surface during brushing, it is an indication that the previous cleaning was not complete.

Dipping in hot flux solutions is sometimes used but is not so satisfactory, as even clean pieces will usually show bare spots after dipping. These bare spots oxidize during heating and, as the brazing alloy will not flow on oxidized metal, are frequently the cause of unsound joints.

Dry flux is occasionally used. To get better adherence of the flux, the joint should be warmed before applying the flux. Complete coverage of the surface by this method is difficult, and it is not recommended.

Flux pastes are customarily made with water. The evaporation of the water during heating results in some bubbling and puffing of the flux. Where this is objectionable, the fluxes may be made of fused or water-free salts made into a paste with alcohol or some other organic vehicle that does not carbonize readily.

Assembling and Jigging. After fluxing, the parts to be brazed must be assembled. Where it is possible, it is advantageous to preplace the brazing alloy. Between flat surfaces, thin sheet or washers may be used. On tubular members, rings made of rectangular strip or round wire are used. These rings may be inserted in grooves cut in the tubes or laid on projecting shoulders. It is preferable to place the alloy inside the joint away from the direct source of heat and in intimate contact with the parts.

Otherwise, as the brazing alloy is usually of lighter gauge than the parts, it heats more rapidly than the assembly and may melt and fall off before the assembly is heated to the brazing temperature.

The brazing alloy is distributed through the joint chiefly by capillary action. However, gravity does help, particularly in the initial flow, and this should be considered in the placement of the alloy in the joint.

Many joints are so designed as to be self-supporting, but on some joints external jigging is required. This is an individual problem with each assembly and sometimes requires considerable ingenuity. The jig should be as simple and as light as possible. The contact area between the jig and the portion of the assembly adjacent to the joint should be kept to a minimum. A heavy jig in close contact with the joint will conduct sufficient heat away to make the heating of the joint to the brazing temperature difficult.

Heating. Several different methods of heating are used in silver brazing. The choice of the method depends on such factors as the size and shape of the pieces and the quantities to be brazed. Regardless of the source of heat, it is important that both members of the joint are heated uniformly and reach the brazing temperature at about the same time. In general, the shorter the heating time, the better, for with a long heating cycle the parts become oxidized excessively, and the flux becomes saturated with oxide so that it is no longer effective.

When a heavy section is being joined to a light section, most of the heat should be applied to the heavy part to avoid overheating and oxidizing the light section. The brazing alloy tends to flow towards the hotter section, and if one section is heated to the brazing temperature too soon, the brazing alloy may flow over the heated area rather than into the joint. Another consideration, in the case of joining dissimilar metals, is differences in heat conductivity. In brazing copper to steel, for instance, the steel with a low heat conductivity will heat rapidly, while the copper will tend to draw the heat away from the joint. This difference in heat conductivity may more than offset effects caused by differences in mass.

Torch Heating. The common types of torches used for silver brazing are air-gas, air-acetylene, oxygen-gas, and oxyacetylene. As a rule the air-gas torches give the least heat, and the oxyacetylene torches give the most heat. Air-gas torches are available not only for city gas but also for natural gas, butane, and propane.

In brazing, the size of the torch should be sufficient so that the required heat can be obtained while using a neutral or slightly reducing flame. The torch should be kept in motion to distribute the heat uniformly over the joint area. Preheating slightly away from the joint until the flux partially fuses and adheres firmly to the metal is advisable as a heavy blast of the flame in the initial stages may blow the flux off and leave bare, oxidized areas.

If the brazing alloy is fed by hand from the outside, the parts to be brazed should be heated slightly above the melting point of the brazing alloy before the alloy is applied. When this temperature is attained, the brazing alloy, previously coated with flux, is brought in contact with the joint and, by momentarily applying the torch to the brazing wire or strip, sufficient alloy is melted to fill the joint. The size of the wire or strip selected should be large enough so that not more than an inch or two of alloy needs to be melted. If the joint is uniformly heated, the alloy will flow over the entire surface from one point. Where long joints are being brazed, it may not be possible to have the entire joint at the brazing temperature at one time, and it will then be necessary to heat the joint in sections applying the brazing alloy at several points.

Bonding of the alloy with the base metals is practically instantaneous at the brazing temperature, and prolonged heating after flowing of the alloy should be avoided as the molten alloy will absorb gases from the flame. Absorbed gases are released when the alloy solidifies and may be trapped in the joint causing unsoundness.

Another common cause of poor brazes is the application of the brazing alloy before the work is at the proper temperature. When the work is too cold, the brazing alloy will "ball up" on the surface. The balling up tends to raise the brazing alloy above the protective film of flux exposing it to direct oxidation. The tendency is then to overheat in an attempt to flow the oxidized alloy, but instead of correcting the trouble, this exaggerates it. The proper method consists of cooling the joint sufficiently to permit applying more flux and then reheat carefully to the brazing temperature.

Torch heating can be adapted readily to automatic, high-production jobs by passing the work through a series of stationary burners on rotating tables or endless chains. Production of several hundred small parts per hour can be attained in this way with a relatively small capital investment.

Furnace Heating. Brazing is frequently done in standard types of heat-treating or annealing furnaces. Both batch-type and continuous-type furnaces, with or without protective atmospheres, are used. In general, the furnace is preheated to a temperature several hundred degrees above the melting point of the brazing alloy so that the parts are heated rapidly, and the time in the furnace is regulated so that the assembly is only heated sufficiently to properly flow the brazing alloy. Preplaced brazing alloy must be used and the parts jigged to hold them securely in place.

Reducing atmospheres are helpful in keeping the parts clean and in reducing the amount of subsequent cleaning. Flux is usually essential even in a reducing atmosphere, but the life of the flux is greatly increased. This is of material benefit when large pieces requiring prolonged heating to attain the brazing temperature are being brazed.

Induction Heating. Because of the rapid and highly localized heating that can be obtained with induction heating this method is being extensively used. Successful use of this method depends largely on the proper design and placement of the heating coils. The makers of the equipment are prepared to supply such coils and should be consulted for advice. This method merits consideration where there are large numbers of an item to be brazed.

With induction heating the heat is developed mainly at the surface and reaches the joint surfaces by conduction. As the heating cycle is very short, there is necessarily a steep thermal gradient between the surface and the joint area except in case of very thin sections. This results in a greater variation in the expansion of the parts than occurs with slower heating methods which must be considered in determining clearances. Contrary to the usual silver brazing practice, press fits are frequently used on assemblies where the coil is placed externally. The intimate contact between the parts also assists in the heating of the inner parts by conduction. Conversely, if the heating is done from the inside, larger clearances are required, or the expansion of the inner part will produce a fit at the brazing temperature too close to allow the brazing alloy to flow into the joint.

Salt-bath Heating. Molten salt baths are also used for heating. They have been particularly useful when a large number of closely spaced joints are to be brazed, as in radiators or heat exchangers. The best results have been obtained when the brazing alloy can be inserted in the joint and not directly exposed to the salt bath. While the salts used are chemically active in reducing oxides, it is customary to coat the joint surfaces with silver brazing flux to get more positive fluxing in the joint. When this is done, care must be taken to dry the flux thoroughly before dipping the assembly in the bath as any moisture present will react with the molten salts with explosive violence.

When the brazing alloy cannot be inserted in the joint but is placed in the form of rings on the outside, the assembly may be dipped into the salt up to the joint and the joint heated by conduction rather than directly from the salt. Another method consists of preheating by partial immersion and then total immersion an instant before the assembly is at the brazing temperature. If these methods are not followed, the light, externally placed ring will melt before the assembly reaches the brazing temperature and will fall off the joint.

One application of salt-bath brazing has been the combination of the case hardening and brazing in one operation in cyanide baths.

Alloy Baths. Molten alloy baths have been used for joining small parts when the control of the temperature and the localization of the heat is difficult by other methods The brazing alloy is melted in a thermostatically controlled crucible and covered with a suitable flux. The parts to be brazed are dipped through the flux into the bath and held there until the alloy flows onto the joint. Large quantities of fine enameled wire for electrical devices are brazed in this manner.

The composition of alloy baths will vary either by volatization of low-melting constituents, such as zinc, during prolonged heating or by solution of metal from the parts being joined. As this will change the melting point of the alloy, the composition of the bath must be controlled either by suitable additions or by occasional replacement.

Electrical-resistance Heating. Tongs have been developed in which the work to be brazed can be clamped between two carbon blocks. Current is passed through this circuit and the carbon blocks are heated to a red heat by resistance. This heat is transferred to the work primarily by conduction. The equipment may be either portable or stationary. It has the advantage of heating and cooling the joints under pressure, thus obtaining strong joints with the minimum amount of alloy. Jigging is usually unnecessary as the pressure clamps will hold the work in position. Heating is localized at the joint area and may be readily controlled.

Spot welders may also be adapted to this type of heating. With spot welders either copper or carbon electrodes may be used. Copper electrodes are usually used on parts having low electrical conductivity, and the resistance of the work itself is used to develop the heat. Carbon electrodes are used on high-conductivity materials where the resistance of the work is too low to generate the required heat. By judicious combination of copper and carbon electrodes, dissimilar materials of widely varying conductivity can be brazed. Tungsten tips may be substituted for the carbon electrodes when long life of the electrodes is desirable.

Flux must be used with this as with other silver brazing processes. As the work is in the electrical circuit and as dry flux is a poor conductor of electricity, the flux should be used as a thin paste and should not be allowed to dry out before the current is passed through the circuit. Otherwise, a heavy surge of current is necessary to break through the resistance offered by the flux, and this may even melt the parts being brazed.

Final Cleaning. Final cleaning consists of the removal of residual flux from the joint area and pickling to remove oxides formed on the parts. The flux is likely to corrode the parts if it is not removed. The corrosive effect is seldom sufficient to damage the assembly seriously, but it is unsightly.

Hot water is generally sufficient to remove the low-melting fluoride containing fluxes. Quenching the assembly after brazing below a red heat but while it is still warm will materially assist in cracking and flaking the fused flux off the work.

Flux that has become saturated with oxides during brazing is only difficultly soluble in water. A warm dilute sulfuric acid or hydrochloric acid pickle will assist in the removal when this occurs. However, such a condition is indicative of faulty brazing practice. It is the result of either too long a heating period, too high a brazing temperature, or the use of too little flux. More liberal use of flux on the outside of the joint will, as a rule, keep the concentration of oxide in the flux low enough to correct this condition.

Proper control of the amount of brazing alloy used will avoid the necessity of the removal of excess brazing alloy. This is one of the advantages of silver brazing in contrast to other processes where large quantities of excess metal are generally used, the removal of which makes the final cleaning cost a significant portion of the cost of making the joint.

CHARACTERISTICS OF SILVER BRAZING ALLOYS

Table 12-9 gives the composition and properties of a representative group of silver brazing alloys. Many other compositions are possible and have been used commercially, but with one or another of these alloys practically any silver brazing job can be done. The selection of a particular brazing alloy depends upon different factors, such as composition and melting points of the metals to be joined, requirements as to color, temperatures, and stresses and corrosion conditions that the joints will be subjected to in use. The cost of the alloy will vary with the silver content, but as the amount of alloy used in a joint is generally small, other considerations, such as the shorter heating time and less damage to the parts by the lower temperature, will often more than offset the greater cost of the alloys with higher silver content.

Pure metals will melt at a single temperature, but most alloys melt over a temperature range. The limits of this range are defined in Table 12-9 by the temperatures given in the columns headed Melting Point and Flow Point. The melting point is the temperature at which, on heating, a part of the alloy starts to become liquid. The flow point is the temperature at which the alloy flows freely. In between these two temperatures the alloy contains both solid and liquid and is in a slushy condition. The part of the alloy that is liquid is of different composition from the part that is solid.

The melting point is akin to what is technically known as the solidus, and the flow point is similar to the liquidus of the constitutional diagram of the particular alloy system. Actually, however, certain brazing alloys flow freely and are regularly used below the true liquidus.

In making a brazed joint the members joined should be heated above the flow point, and this is the temperature of main interest to brazing.

Table 12-9. Typical Silver Brazing Alloys

Number	Chemical composition						Melting point, deg F	Flow point, deg F
	Ag	Cu	Zn	Cd	P	Ni		
1*	10	52	38				1450	1565

‡ Proprietary alloys.

The length of the melting range varies widely with the alloy, in some cases being as much as several hundred degrees and in others only a few degrees. In torch brazing, when the alloy is hand-fed and almost instantly melted, the length of the melting range is of little consequence and has no material effect on the flow of the alloy. On the other hand, when other methods of heating are used and when the alloy is preplaced and is heated slowly through its melting range, along with the work, the length of the melting range is of importance. The part of the alloy to melt first is likely to flow into the joint leaving a lump of a higher melting alloy behind. As the temperature is raised, this process continues with the composition of the residue constantly changing. The composition of the residue may change to such a degree, and its flow point be raised to such an extent, even above the original flow point of the alloy, that the residue will not melt even at several hundred degrees superheat. The final result is that the lump is left on the joint after the brazing is completed, only part of the alloy is actually used, and a smooth fillet is not obtained.

With short-melting-range alloys the change from solid to liquid is almost instantaneous, even on slow heating, and the alloy flows more freely without the sluggishness of the long-range-melting alloys.

Both types of alloys have advantages. The short-melting-range alloys are preferable for slow heating, as in furnace brazing, because they are not so sensitive to changes in the rate of heating, and they will flow readily into very narrow spaces. They tend not to fillet well, however, and tend to run through the joint without filling gaps which the long-melting-range, more sluggish, alloys, will completely fill. Therefore, when close fits are not possible, the long-melting-range alloys usually give better results.

The melting point of the brazing alloy is sometimes of importance because of its effect on the strength of the joint just below the brazing temperature. A joint is weak during the period when any part of the alloy is molten. Therefore, on cooling from the brazing temperature or on any subsequent heating, care must be used not to strain the joint while above the melting point of the alloy.

Information is frequently sought regarding the tensile strength and other physical properties of silver brazing alloys in the forms in which they are supplied to the trade. Such information is of little or no value in determining the suitability of an alloy for brazing or for predicting the strength of a brazed joint. The strength of the completed joint is dependent on so many factors that initial physical properties of the alloy are of minor importance. A good joint depends in a large degree on design and brazing technique. The properties of the metals being joined are of major importance, as with the same brazing-alloy joint strengths varying from about 30,000 psi on copper to 130,000 psi on high-tensile-strength steels can be obtained. In general, the strength will vary almost directly with the strength of the metals being brazed.

Shear strengths of brazed-steel joints will be roughly 20,000 to 50,000 psi, again depending upon the design and the properties of the material being joined. The maximum load which can be applied to a joint in shear is limited by the load required to start stretching any member of the joint. As soon as stretching occurs, high stresses occur at the edge of the joint, and the joint will fail by tearing rather than by true shear. Increasing the shear length beyond that required to withstand this load will not increase the total load the joint will carry before failure.

The strength of joints will also vary with the temperature. Short-time tests on steel brazed with silver alloys indicate that at 600°F the joint strength is about 50 per cent of that at room temperature. At 800°F the strength is roughly 25 per cent of room strength, and at 1000°F only about 10 per cent of the original strength remains.

EFFECT OF BRAZING TEMPERATURE ON METALS JOINED

An important consideration in brazing is the effect of the brazing temperature on the properties of the metals being joined. The temperatures required are above the annealing temperatures of practically all nonferrous alloys, and these alloys will lose any hardness which has been produced by cold working. However, the annealing effects can be minimized by localized and rapid heating, and in any case the relatively low temperature required as compared to other welding processes decreases the danger of material impairment of the properties of the base metals.

Heat-treated carbon steels, such as the usual carbon tool steels, will also be softened at the temperatures required for silver-alloy brazing. It is possible, however, to select a brazing alloy from Table 12-9 with a melting point sufficiently high to permit heat-treating subsequent to the brazing operation. At times the brazing and the quenching of the steel from temperatures of 1400°F or above are combined in one operation. The success of this procedure depends largely on the stresses introduced during the quenching operation. As the joint itself is weak at these temperatures, the assembly should be designed so that only compressive stresses are applied to the joint. Similarly case-hardening low-carbon steels and brazing are occasionally successfully combined in one operation.

The structural alloy steels, such as SAE 4130, may be heat-treated prior to silver brazing and if brazed rapidly with one of the lower melting silver brazing alloys will retain practically all the hardness and strength introduced by the heat-treatment.

Heat-treated and tempered high-speed tool steel may also be brazed without appreciable loss in hardness by means of silver brazing alloys melting below 1200°F. Silver brazing is frequently used for repairing broken tools or for brazing high-speed-steel tips to low-carbon-steel shanks. Although the usual tempering temperature for high-speed steel is about 1050°F, the softening of the steel is a time-temperature reaction, and with a short heating cycle it is entirely practical to braze the steels at temperatures in the vicinity of 1200°F without adversely affecting the hardness.

Silver-alloy brazing is used extensively for brazing tungsten-carbide tool tips. In joining tungsten carbide to steel stresses of sufficient magnitude to crack the carbide are often developed because of the difference in thermal expansion of the carbide and the steel. At the low temperature required for silver brazing these stresses are lower than when other methods of joining employing higher temperatures are used, and the losses resulting from the cracking of the carbide are largely eliminated.

Among the nonferrous alloys the brazing of the precipitation hardening beryllium-copper alloys is interesting. The usual procedure for hardening these alloys is to anneal at about 1500°F to form a complete solid solution, quench, and then reheat at a temperature of 500 to 600°F for 1 to 2 hr to precipitation-harden. It has been found that, after the quench from the high-temperature, beryllium-copper can be quickly brazed with a silver brazing alloy at about 1200°F and that the brazed assembly can then be precipitation-hardened by annealing at 500 to 600°F to the same extent as with the usual procedure.

CORROSION

Some reference should be made to the corrosion resistance of silver brazing alloys. They are, in general, highly resistant to the majority of corrosive conditions for which nonferrous alloys are used. Wherever dissimilar metals are used, galvanic corrosion is an important problem. Silver alloys, particularly those of high silver content, are cathodic to many metals and alloys in use under corrosive conditions. As galvanic corrosion is generally in proportion to the relative areas exposed to attack and as the surface exposure of the silver alloy in a properly made joint is small, the attack on the brazing alloy is normally negligible. In addition, the length of the brazed joint is usually long as compared to the surface exposure, and this is a favorable factor in increasing the life of a joint even under adverse conditions.

There are a few conditions which should be noted in which certain silver brazing alloys are seriously attacked. For instance, phosphorus-bearing brazing alloys should not be used where they are exposed to hot gases containing sulfur-bearing compounds as the brazing alloy will gradually disintegrate. Also stainless steels subjected to brines or chlorine compounds, as in marine fittings or dairy equipment, will fail if brazed with most grades of silver brazing alloys. Fortunately, in this case, the addition of a few percent nickel to the brazing alloy will overcome this difficulty and an alloy such as No. 12 in Table 12-9 will give excellent corrosion resistance. Finally, nitric acid in almost all concentrations is a solvent for silver brazing alloys, and the alloys should not be used in solutions containing nitric acid.

GAS WELDING AND CUTTING

BY F. J. KING

Chief Engineer,
The Linde Air Products Company

Although frequently called gas welding and cutting, the process should correctly be called oxyacetylene welding and cutting since oxygen and acetylene are the gases usually used. Other combinations of gases, such as acetylene and air, natural gas and oxygen, or natural gas and air, do not produce flames that are nearly so hot. Consequently they are not often used for welding or cutting but only for heat-treating, brazing, or soldering.

OXYACETYLENE WELDING

Basically, oxyacetylene welding is the bringing together of two pieces of metal and the melting of the edges in contact by the oxyacetylene flame produced at the tip of the welding blowpipe. The molten metal flows together from the two edges until they are completely fused and form one continuous piece after the metal has cooled.

The oxyacetylene flame is also used for heating in cutting, shaping, and flame machining of ferrous metals and as a convenient source of localized heat for a wide variety of operations such as hard facing, flame hardening, flame softening, and flame descaling.

Principles of Operation. With suitable equipment, the operator can produce at will an oxyacetylene flame of the proper size and character for the work at hand. By changing slightly the proportions of oxygen and acetylene used, the chemical characteristics of the oxyacetylene flame and consequently its action on molten metal can be varied over a wide range.

Types of Flames. When an exactly 1-to-1 mixture of oxygen and acetylene is lighted at the blowpipe tip, the resulting flame is called a neutral flame because it neither oxidizes nor carburizes the weld metal. The neutral flame has two sharply defined zones. The inner portion of the flame consists of a brilliant cone from 1/16 to 3/4 in. long, depending on the size of the opening in the tip. Surrounding this is a larger "envelope flame" only faintly luminous and of a delicate bluish color.

When there is slightly more acetylene in the mixture, the flame consists of three zones. There is still a sharply defined inner cone and the bluish outer envelope, but between these is an intermediate cone of whitish color. This flame is variously called an excess acetylene, a reducing, or a carburizing flame.

When there is more oxygen than acetylene in the mixture, the flame has the general appearance of the neutral flame, but the inner cone is shorter, has a sharper point, and acquires a purplish tint. The three types of flame are shown by Fig. 12-29.

Flame Adjustment. It is usual practice when lighting a blowpipe to open the acetylene valve more than the oxygen so that the flame first shows an excess of acetylene. As the blowpipe acetylene valve is closed gradually, the excess-acetylene cone gets smaller and finally disappears completely. The neutral flame is formed just at the point where the excess-acetylene cone disappears. In adjusting for the type of flame desired, it is usual to adjust it first to neutral and then to make the necessary adjustment for the excess-acetylene or excess-oxygen flame as required.

The amount of excess acetylene in the flame is determined by comparing the length of the acetylene feather with the length of the inner cone, measuring both from the blowpipe tip as shown by Fig. 12-30. For instance, a 2X excess-acetylene flame has an acetylene feather that is twice as long as the inner cone; a 3*X* excess-acetylene flame has an acetylene feather that is three times as long as the inner cone.

Similarly, the oxidizing-flame adjustment is sometimes given as the amount by which the length of the neutral inner cone should be reduced, *e.g.*, one-tenth. Starting again with the neutral flame, the operator increases the oxygen (or decreases the acetylene) until the length of the inner cone has been shortened to the desired amount. In some cases the exact adjustment has to be determined by the action of the flame on the molten metal.

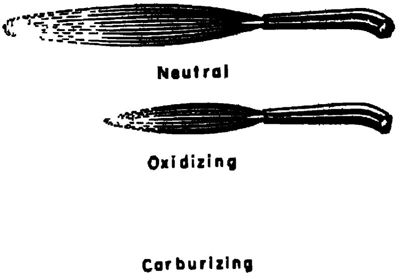

Fig. 12-29. The three types of oxy-acetylene-welding flames.

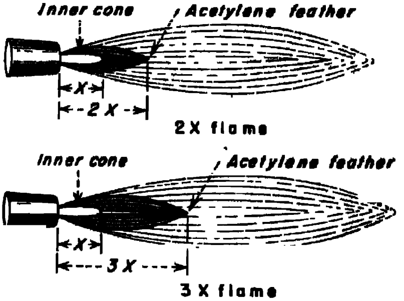

Fig. 12-30. Determining the amount of excess acetylene in a flame.

For welding mild steels, a neutral flame is desirable. For higher carbon and alloy steels, the carburizing flame may be preferable so as to preserve the alloying elements from oxidation. An oxidizing flame is generally used in the fusion welding of bronze and brass to assist in the formation of the protective oxide film. Use of a slightly oxidizing flame in brazing must also take into consideration the possible undesirable effect on the tinning action.

Welding Rods. Because any metal added during welding must have the same properties as the base metal, welding rods of various composition have been devised for

Table 12-10. Welding Data—Ferrous Metals

Metal	Welding method	Flame adjustment	Flux	Welding rod
Steel, cast	Fusion	Neutral	No	Steel
Steel pipe	Fusion	Neutral	No	Steel
Steel plate	Fusion	Neutral	No	Steel
Steel sheet	Fusion	Neutral	No	Steel
	Bronze weld	Slightly oxidizing	Yes	Bronze
High-carbon steel	Fusion	Carburizing	No	Steel
Manganese steel	Fusion	Slightly oxidizing	No	Base-metal composition
Cromansil steel	Fusion	Neutral	No	Steel
Wrought iron	Fusion	Neutral	No	Steel
Galvanized iron	Fusion	Neutral	No	Steel
	Bronze weld	Slightly oxidizing	Yes	Bronze
Cast iron, gray	Fusion	Neutral	Yes	Cast iron
	Bronze weld	Slightly oxidizing	Yes	Bronze
Cast iron, malleable.	Bronze weld	Slightly oxidizing	Yes	Bronze
Cast-iron pipe, gray.	Fusion	Neutral	Yes	Cast iron
	Bronze weld	Slightly oxidizing	Yes	Bronze
Cast-iron pipe	Fusion	Neutral	Yes	Cast-iron or base-metal composition
Chromium-nickel.	Bronze weld	Slightly oxidizing	Yes	Bronze
Chromium-nickel	Fusion	Neutral	Yes	Base-metal composition
Steel castings				25-12 chromium-nickel steel
Chromium-nickel steel (18-8) and (25-12)	Fusion	Neutral	Yes	Columbium stainless steel or base-metal composition
Chromium steel	Fusion	Neutral	Yes	Columbium stainless steel
Chromium iron	Fusion	Neutral	Yes	Columbium stainless steel

Table 12-11. Welding Data—Nonferrous Metals

Metal	Welding method	Flame adjustment	Flux	Welding rod
Aluminum	Fusion	Slightly carburizing	Yes	Aluminum
Brass	Fusion	Oxidizing	Yes	Bronze
	Bronze weld	Slightly oxidizing	Yes	
Bronze	Fusion	Neutral	Yes	Bronze
	Bronze weld	Slightly oxidizing	Yes	
Copper (deoxidized)	Fusion	Neutral	No	Deoxidized copper
	Bronze weld	Slightly oxidizing	Yes	Bronze
Copper (electrolytic)	Fusion	Neutral	No	Copper
	Bronze weld	Slightly oxidizing	Yes	Bronze
Everdur bronze	Fusion	Slightly oxidizing	Yes	Base-metal composition
Nickel	Fusion	Slightly carburizing	No	Base-metal composition
Monel metal	Fusion	Slightly carburizing	Yes	Base-metal composition
Inconel	Fusion	Slightly carburizing	Yes	Base-metal composition
Lead	Fusion	Neutral	No	Base-metal composition

all sorts of ferrous and nonferrous welding. Obviously, it is important that the correct welding rod be selected for any particular welding problem. Allowances are made in the chemistry of good welding rods for the changes that take place in the welding process, so that the deposited metal will be of the correct composition.

Fluxes. No flux is required for the fusion welding of mild and low-alloy steels, but with most commercial nonferrous alloys containing such readily oxidizable ingredients as copper, zinc, aluminum, chromium, or silicon, a flux must be used (see Table 12-10 and Table 12-11 for details). Fluxes should not be substituted for proper cleaning in the preparation of the base metal. The flux should be easily removed upon completion of the work and should have no corrosive action on the finished joint. Fluxes are used to accomplish the following effects:

1. The flux should form a fusible slag with the oxides formed during welding and should float to the top of the molten puddle.
2. The flux should protect the molten puddle from reaction with the gases of the surrounding atmosphere.
3. The flux should clean and protect the surfaces of the base metal and, in some cases, the welding rod during the preheating and welding or brazing.

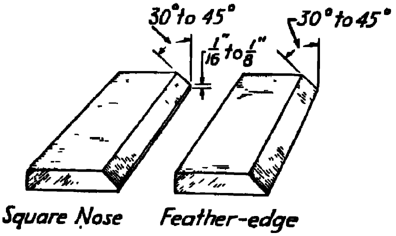

FIG. 12-31. Plate material 1/4 in. or more in thickness is beveled so that a V is formed.

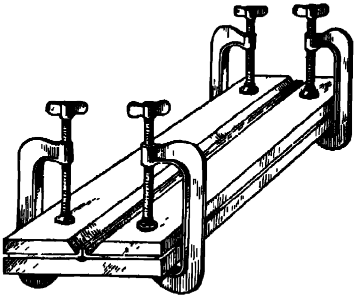

FIG. 12-32. Jig for making butt or flange welds in sheet metal.

Base-metal Preparation. The areas to be welded should be cleaned of scale and dirt of any sort. The edges of abutting plates, which are 1/4 in. or more in thickness, are beveled so that a V is formed as shown by Fig. 12-31. This is done to ensure complete penetration of the fused portion through the base metal. The angle of the vee opening varies from 50 to 90 deg, and a square nose is usually left at the bottom of the joint, although a feather edge is permissible for some work. In plate more than

½ in. thick, a double-vee opening on both sides of the plate is used. Thin sheet is often joined by flanging the edges, butting the flanges against one another, and fusing the flanges, generally without the addition of welding rod. A jig for holding the flanged sheets during welding is shown by Fig. 12-32.

Other joint designs, such as a U contour, are possible, but more expensive to prepare than the simple vee, which can be produced rapidly by flame cutting.

Bronze Welding. Bronze welding is a method of joining iron or steel without fusing the base-metal edges. Consequently, the disadvantages that may occur from bringing the base-metal edges to fusing temperature do not exist, or they are at least minimized. The bronze rod used in the process melts at about 1600°F. This is considerably below the melting point of many commercial metals. It is this fact that makes the process possible.

In bronze-welding, the veed edges are first thoroughly cleaned, then raised to a dull-red heat. In the presence of a suitable flux, the bronze metal from a rod is flowed on so as to form a tinned surface. Successive passes are made as necessary, until the joint is completed.

For joints made of malleable iron and galvanized iron, bronze welding is superior to fusion welding because the base metal is little affected. The malleability of cast iron therefore is preserved, and the coating of galvanized iron is affected only locally.

Multilayer Welding. Multilayer welding is a variation in welding technique that is recommended for joining heavy plate. It is accomplished by depositing rod metal in successive passes along the joint until it is filled. Since the "bite" taken with each pass is small, the weld puddle is reduced in size. The small puddle is more easily controlled, and thus the operator can avoid oxides, slag inclusions, cold shuts, and lack of fusion with the base metal. The major advantage of this process is, however, the increase in ductility of the deposited metal owing to the grain refinement resulting from the welding heat of each successive layer. The final layer, of course, will not possess this refinement unless the blowpipe is passed over the surface again to normalize the metal deposited in the last pass.

Oxyacetylene Welding Equipment. There are two general types of oxyacetylene blowpipes: medium and low pressure. Low pressure blowpipes make use of what is known as the injector principle. A cross section of this type of blowpipe is shown by Fig. 12-33. The oxygen passes through a small opening in the injector and produces a suction which draws acetylene into the oxygen stream. In the medium-pressure blowpipe, cross-section diagram shown by Fig. 12-34, the oxygen and acetylene are regulated by valves in the torch to approximately the same pressures. The mixing chamber serves only to blend the gases thoroughly before they enter the tip.

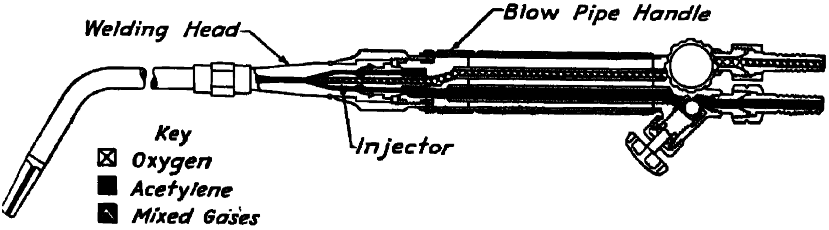

FIG. 12-33. Section diagram of injector-type welding blowpipe. It can operate on low- or medium-pressure acetylene.

Selection of Torches. There are a number of models of oxyacetylene-welding blowpipes. The choice of a blowpipe depends on the nature of the work to be done. For very small flames necessary on thin sheets or other delicate work, there are tips available having orifices as small as 0.018 in. The acetylene flow through these tips is approximately 1 cu ft per hr, and the blowpipes with which the tips are used are very small and light in weight.

Where large sections are being welded and a great deal of heat is needed, tips with orifices as large as 0.250 in. can be secured. Also, there are multiple-flame tips that have acetylene consumptions as high as 250 cu ft per hr. These multiflame tips are more often used for heating than actual welding operations.

Machine Equipment. For the production of certain welded articles, machine welding has been found to produce welds that are better and more uniform in quality and, in most cases, more economical than hand welding.

The oxyacetylene welding machines are designed for three types of welding: fusion welding of steel with welding rod added, fusion welding of steel without the addition of welding rod, and bronze welding. The last type requires the use of a flux, and is more expensive than fusion welding, but possesses the virtue of greater speed as well as other advantages which have been discussed. The edges must be sheared correctly and held in contact during welding.

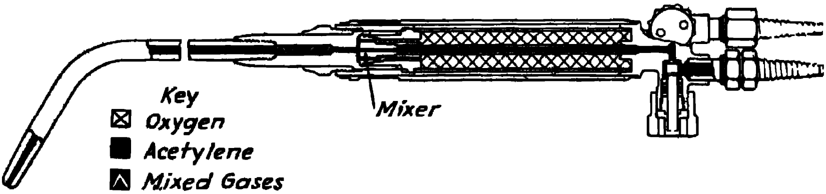

FIG. 12-34. Section diagram of welding blowpipe designed for medium-pressure operation.

Joint detail is very important in the fusion welding of sheet steel without the addition of welding rod. The edges must be sheared correctly and held in contact during welding. To do this, side pressure must be applied to the clamp jaws in order to force the edges together. To avoid deformation due to contraction stresses, jigs and clamps should be heavy enough to absorb heat from the workpiece quite rapidly. When production rates are high, or when items welded are small, water-cooled jigs should be used to absorb the heat quickly. This type of operation produces a flush weld with a minimum of reinforcement. Pieces with curved sides that cannot be made by rolling or bending flat sheets can also be machine welded. The parts may be stamped or drawn in two halves. These halves are then placed together in a jig and positioned so that the seams are in the same horizontal plane. The joints are then welded simultaneously with two welding heads moved by a common carriage. This method of welding will be somewhat slower because the horizontal-vertical position of the weld requires a smaller weld puddle.

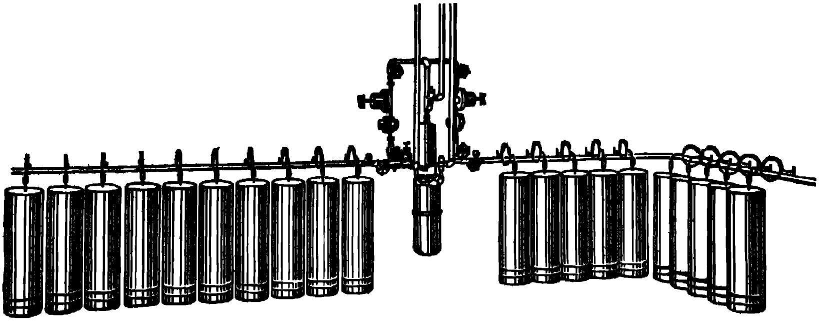

FIG. 12-35. Cylinders of acetylene connected to a manifold.

Gas Supply. Acetylene is distributed in steel cylinders containing a porous filler and acetone, in which the acetylene is dissolved. The most common cylinder sizes have rated capacities of 100, 275, and 300 cu ft.

The gaseous acetylene should not be allowed to discharge too rapidly from the cylinder because a fine mist of acetone may be carried along with the gas. To avoid such an occurrence, the rate of discharge per cylinder in cubic feet per hour should not exceed one-seventh the *rated* gas content capacity of the cylinder in cubic feet. Where the apparatus consumes acetylene faster than the recommended discharge rate for a single cylinder, the acetylene should be supplied by two or more cylinders discharging simultaneously through a suitable manifolding device as shown by Fig. 12-35.

Acetylene can also be made as it is used. Acetylene generators produce the gas by reaction between calcium carbide and water. There are two general types: the medium-pressure type produces acetylene at from 1 to 15 psi; the l-p type generates acetylene at less than 1 psi. Both types are available in a wide range of sizes for both stationary and portable service. A typical generator for stationary service is shown by Fig. 12-36.

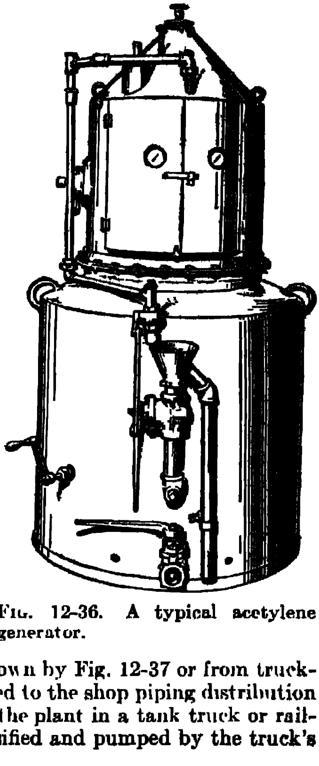

FIG. 12-36. A typical acetylene generator.

The small portable generators have carbide capacities of about fifteen pounds, with generating capacities of approximately 30 cu ft per hr. In contrast, some of the large stationary industrial generators have carbide capacities of 1 ton per hr with generating capacities of thousands of cubic feet of acetylene per hour.

Oxygen for commercial purposes is supplied in seamless steel cylinders. The gas is compressed to 2,200 psi, at 70°F. Two sizes of cylinders are available: the larger and more common holding oxygen equivalent to 244 cu ft at 1 atmosphere and 70°F, the smaller cylinder containing half this volume.

In order to supply the large quantities of oxygen required in some industries, the compressed gas may be obtained from an appropriate number of cylinders connected to a manifold as shown by Fig. 12-37 or from truck-trailer storage units, either of which can be connected to the shop piping distribution system. Oxygen in liquid form may be delivered to the plant in a tank truck or railroad tank car. The liquid oxygen may then be gasified and pumped by the truck's apparatus into the plant's storage facilities, or discharged as liquid into a converter which automatically furnishes gaseous oxygen to the plant's distribution piping system.

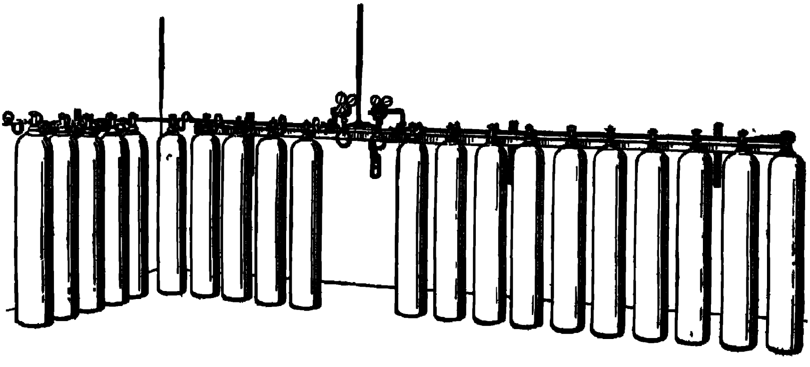

FIG. 12-37. Oxygen cylinders connected to a manifold.

Manifolds and Pipe Lines. Centrally located supply units with piping systems to conduct the gases to the point of use are a decided advantage, since cylinder and regulator handling is considerably reduced, cylinders are removed from working areas in the shops, a master control of available working pressure is obtained, and a continuous supply of gas is afforded.

The manifolds and pipe lines for oxygen are different from those for acetylene because the gases have such different natures. The oxygen system is generally operated at pressures from 50 to 100 psi. Pure oxygen at these pressures violently supports combustion. The pressure of the acetylene system is not greater than 15 psi, but the gas is extremely flammable.

At the blowpipe station, the high oxygen and acetylene pressures are reduced to working pressures by the use of regulators. These instruments automatically reduce the pressure to the desired value and maintain it there without fluctuation.

At all points where gases are drawn off to supply a blowpipe, or other consuming device, a regulator or hydraulic flash arrester is required for the acetylene if the gas is delivered by a manifold or from medium-pressure generators. In exceptional cases, where all the operators are doing the same work and using the same oxygen pressure, the oxygen station-regulator can be dispensed with and regulation secured at the manifold. For acetylene from l-p generators, a suitable waterseal or hydraulic flash arrester is used at each outlet.

The purpose of the water seals is to prevent the passage of oxygen back into the acetylene lines. The regulators at acetylene outlets also serve the same purpose. Water-seal devices should be installed where each important branch line joins the main.

Station outlets for welding and cutting should be provided with shutoff valves so that service regulators may be removed at will, either for repair or because regulators need not be provided as permanent attachments to all stations at once. Acetylene-station outlets are frequently provided with mechanical check valves in addition to regulators.

Oxyacetylene Welding Applications. Oxyacetylene welding is used on the whole range of commercial ferrous and nonferrous alloys. As in any welding process, however, physical dimensions and chemical composition must limit the weldability of certain materials and pieces.

In fusion welding, the temperature range through which the metal is taken is practically the same as that of the original casting procedure. The base metal in the weld area loses those special properties that were given to it by heat-treatment or working. Therefore the ability to weld such materials as high-carbon and high-alloy steels is limited by the equipment available for heat-treating after welding. However, such metals are commonly welded with success, when the size or complicated nature of the piece does not prohibit heat-treating operations.

For wrought-iron and "foolproof" or plain carbon steels, the welding procedure is straightforward and offers little difficulty to the operator. Sound welds are produced in other materials by appropriate changes in technique, heat-treating, preheating, and fluxing.

The oxyacetylene process can be used for welding thicknesses of metal up to that used in heavy piping and for problems normally encountered in maintenance and repair.

Iron and Steel. As has been indicated, the low-carbon, low-alloy steels, cast steels, and wrought iron are the materials most easily welded by the oxyacetylene process. Only a simple technique and no fluxes are required.

In oxyacetylene welding, straight-carbon steels over 0.70 per cent of carbon are considered high-carbon steels, and necessitate special care to maintain their particular properties. Alloy steels of the type called "air hardening" also require precautions to maintain their properties even though the carbon content may be 0.35 per cent or less. The joint area is usually preheated in order to slow the cooling of the weld by conduction into the surrounding base metal. This prevents the hardness and brittleness associated with rapid cooling. The operator should use a carburizing flame, and should be careful not to overheat the base metal and burn out the carbon.

For stainless and similar steels, several modifications in procedure are made. Because of the higher content of chromium, these steels have a lowered heat conductivity. Therefore, a smaller flame is recommended than for equal thickness of plain carbon steel. A neutral flame is used because the chromium easily oxidizes and a flux is used to dissolve oxides and protect the weld metal. A high-chromium composition welding rod supplies metal to fill the weld.

Cast iron, malleable iron, and galvanized iron all present particular problems in fusion welding of any sort. In cast iron, the gray cast-iron structure can be maintained through the weld area by use of a preheat, a flux, and an appropriate cast-iron welding rod.

Malleable iron cannot be fusion-welded. Remelting offsets its properties which depend entirely on a long and expensive heat-treating and working operation. Bronze welding affords an excellent method of joining without excessive heating. Therefore, it is recommended for malleable iron and for galvanized iron, in order to preserve the galvanizing. This method is also used in joining dissimilar metals, and in sheet-steel fabrication.

Nonferrous Metals. As is the case with the various ferrous alloys, the particular properties of each nonferrous alloy must be considered in the technique used for welding it. When the logical precautions are taken, little difficulty due to the nature of the metal should be encountered.

For instance, aluminum gives no warning by change in color prior to melting but appears to collapse suddenly at the melting point. Hence practice in welding it is required to learn to control the rate of fusion. Aluminum and its alloys also suffer from hot shortness. Therefore they should be adequately supported at all points heated during the welding. Finally, any exposed aluminum surface is always covered with a layer of oxide and forms a fusible slag which floats on the top of the molten metal.

In copper welding, allowances are necessary for chilling of the weld owing to the very high thermal conductivity of copper. Also, considerable distortion can be expected in copper because the coefficient of thermal expansion is higher than in other commercial metals. These characteristics obviously pose difficulties which must be surmounted in satisfactory welding.

These examples will suggest the type of problems encountered in oxyacetylene welding, as well as the solutions.

Surfacing Operations. In hard-surfacing, a layer of metal with the special properties desired is deposited from a welding rod and sweated on to the base metal surface. In this way, a very hard, abrasion-resistant surface of alloy may be spread on a mild steel part, and so prolong the part's usefulness. The hard-surfacing operation offers a simple, low-cost means of producing parts that have two to twenty-five times the life of steel under similar conditions of abrasion.

Broken edges, gear teeth, and mismachined surfaces can be built up by depositing layers of metal that are like the base in composition. The built-up surfaces can then be machined and heat-treated so that they will have the same properties as the original piece. This application makes it possible to reclaim all sorts of damaged pieces, and results in savings in part costs and replacement time.

Fields. The process is widely used in such fabricating industries as: sheet metal, tubing, aircraft, industrial piping, and automotive. It is also used gainfully in laying pipe lines and in shipyards, as well.

"*Maintenance and Repair.*" The one field in which the process is most widely used and accepted is in maintenance and repair, where its flexibility and mobility make for great savings in time and labor. Oxyacetylene welding has been shown to be particularly suited to the needs of steel mills, railroad shops, machine shops, and automobile-repair shops, as well as in shops devoted entirely to welding, whose main business may be in repair of many sorts of small industrial and household equipment.

OXYGEN CUTTING

Equipment and Operation. Although the process is variously called oxyacetylene cutting or flame cutting, "oxygen cutting" is the preferred technical term.

When iron or steel is heated white hot and a stream of pure oxygen is directed against it, the metal burns rapidly, producing the magnetic oxide of iron (Fe_3O_4) with

* The metal should be preheated before cutting to prevent hardening of the metal in the face of the cut. Usual preheating temperatures range from 500 to 900°F. Preheating is used for certain grades to facilitate cutting. If not preheated, a heat treatment, furnace or otherwise, should follow to improve or recondition the structure of the cut surface, provided the material is kept warm between the time of cutting and heat-treatment.

† Material should be preheated as described under *.

‡ Heat-treating after cutting may be necessary if the carbon content is on the high side.

the liberation of a considerable amount of heat. The oxide formed is in the molten state and flows or is blown away, exposing more metal to the action of the oxygen. Because of the chilling effect of the surrounding metal, it is necessary to continue to supply heat at the point of cutting even though the cutting action liberates heat. The preheating flames of the blowpipe serve to raise the temperature of the metal to the reaction point and thereby supply the heat necessary to keep the reaction going.

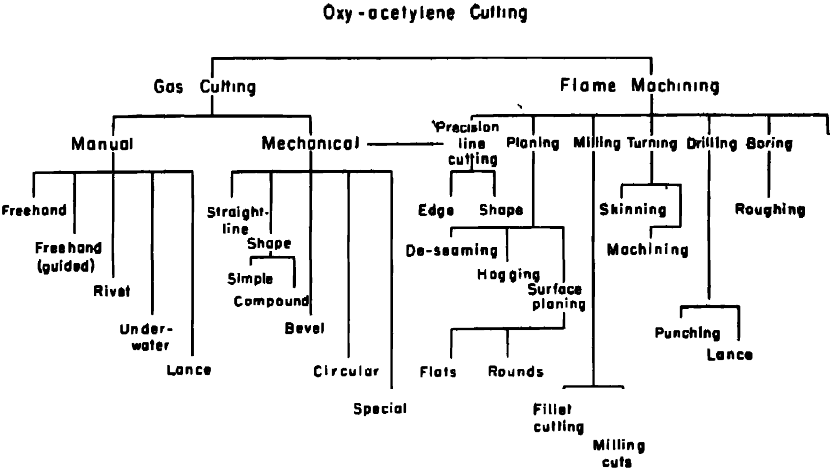

Fig. 12-38. The scope of oxygen-cutting processes is illustrated by this diagram.

Scope of Process. The variety of operations performed by oxygen cutting is shown graphically by Fig. 12-38. Only the more important of these operations will be discussed in this subsection. The chart will serve as a guide for obtaining further information if it should be needed. Carbon- and low-alloy steels are readily oxygen-cut by the ordinary straight-line technique. Table 12-12 lists the steels that can be cut by regular or special methods. Certain high-alloy steels, such as stainless steels,

* The cut surfaces of the cast irons in heavy sections are hardened by the cutting operation and should be heat-treated if they are to be machined after cutting.

† Heat-treatment usually is necessary to counteract harmful effects of the heating produced during the cutting operation unless the metal contains a stabilizing element to prevent such heat effects.

show considerable resistance to oxygen cutting. These materials, as well as the nonferrous alloys can usually be cut by special techniques. A detailed list of the materials requiring special cutting techniques is given in Table 12-13.

Thicknesses and Tolerances. Speed ranges for various thicknesses of plain carbon steel, using different types of nozzles, are given in Table 12-14.

Table 12-14. Cutting-speed Ranges for Various Thicknesses of Metal

Thickness of metal, in.	Machine cutting speed, in./min		
	Standard cutting nozzles	Precision cutting nozzles	High-speed cutting nozzles
Up to ⅛	19-27		
⅛	18-26		
¼	17-25	16-21	
⅜	16-24	14-19	
½	15-23	13-18	26-28
¾	13-21	11-15	22-25
1	12-18	7-10	21-24
1½	11-15	6-8	14-16
2	10.0-14.0	5-7	12-15
3	7.8-10.9	5-7	11-14
4	6.4-8.9	4-6	10-13
5	5.4-7.4	4-5	8-11
6	4.7-6.5	4-5	7-10
8	3.7-4.9	3-4	6-9
10	2.9-3.8		3-7
12	2.4-3.0		3-6
16	3.0-3.5		
18	3.0-3.5		

The final tolerance on any oxygen-cut part is affected by three items: machine accuracy, oxygen-jet accuracy, and the distortion factor. The newer machines will follow a line or duplicate a pattern to within 0.015 in. The oxygen jet will remain within about 0.006 in. of a line so that the combined accuracy is not better than 0.021 in. The distortion factor is the allowance that must be made for the thickness of the material. The bottom of the cut may be out of line with the top of the cut by as much as 0.005 in. per inch of thickness.

Quality of Cut. The quality of the cut varies with the nozzle used, the speed of cutting, and the gas pressures. Shapes or parts that are to fit closely together with little or no finishing require high-quality cuts. In scrapping or demolition work, the object is merely to separate one part from another and so the cut surface is not important. Any discussion of the quality of an oxygen cut necessarily involves the consideration of "drag." "Drag" (sometimes called "lag") may be defined as the amount by which the bottom of the cut lags behind the top expressed as a percentage of the plate thickness. Straight-line cuts may be made with considerable lag without much detrimental effect, since the drag lines lie within the plane of the cut and do not prevent both top and bottom edges from being left clean and sharp. However, in shape cutting less drag is permissible, since the bottom of the contour would tend to come out differently from the top. Such cuts must be made with small drag and are known as "high-quality" cuts. High-quality cuts require somewhat more oxygen than cuts that have long drags and barely penetrate the material. Precision-machine cuts are necessarily of the high quality.

Equipment Required for Oxygen Cutting. The implements that permit the controlled use of the combined oxygen-jet and oxyacetylene preheat flames, is called a "blowpipe" or "torch."

Cutting Blowpipe. Blowpipes are of two types: first, those in which the fuel gas and oxygen for the preheating flames are mixed at the tip; and second, those in which the mixing takes place in the head or some location back of the head. This latter type is designated as the premixed type. If both the oxygen and acetylene are under appreciable pressure, the blowpipe is designated as a "medium-pressure" blowpipe. If the fuel gas is at a lower pressure, generally a fraction of a pound per square inch, an injector is necessary to mix it with the oxygen and the blowpipe is designated as a "low-pressure" or "injector" type. A cross section of a typical low-pressure blowpipe is shown by Fig. 12-39.

Machine-cutting Blowpipe. Machine-cutting blowpipes are usually straight and usually equipped with a rack that engages a pinion in the blowpipe holder, to adjust the height of the blowpipe above the work. Special heavy-duty machine-cutting blowpipes are available for cutting heavy sections or hot steel. Such blowpipes are usually water-cooled, operate on medium-pressure acetylene, and require a surprisingly low cutting-oxygen pressure.

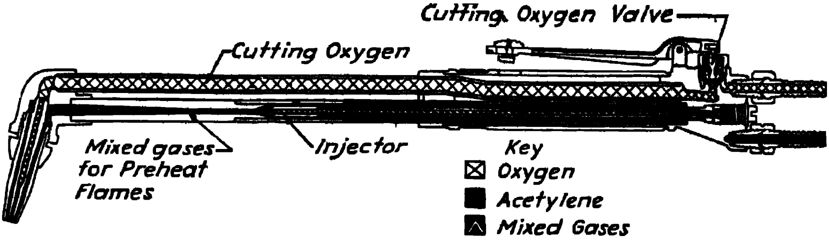

FIG. 12-39. Cross section of "low-pressure" or "injector"-type cutting blowpipe.

Cutting Nozzles. Simply by changing the size of nozzle, a single cutting blowpipe can be used to cut a wide range of metal thicknesses. The nozzles for the modern cutting blowpipes are made with the oxygen-cutting jet surrounded by several preheating flames as shown by Fig. 12-40. With this arrangement, the blowpipe can be moved in any direction without losing the effect of the preheating flame.

In addition to the standard cutting nozzles, there are several special-purpose nozzles. High-speed cutting nozzles, precision cutting nozzles, gouging nozzles, and rivet-cutting nozzles are examples of such special-purpose equipment.

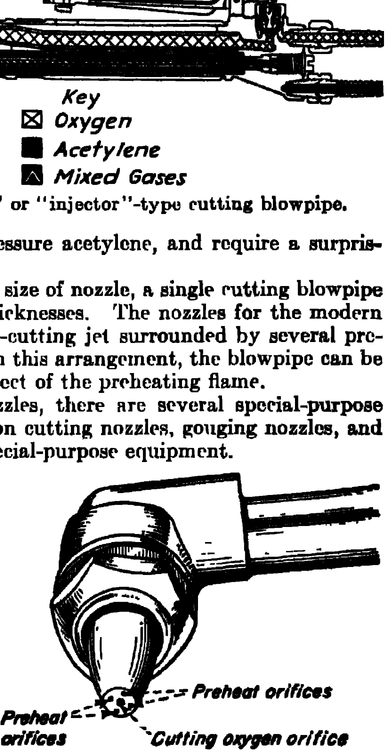

FIG. 12-40. The usual type of cutting nozzle for manual operation.

Cutting Machines. Cutting machines really consist of an oxygen-cutting blowpipe and a means of propelling it. They may be simple and light and usually of limited application or heavy, complicated, and quite versatile. In this subsection are illustrated a few of the typical oxygen-cutting machines selected to show the wide range available.

Small cutting machines weighing under 100 lb are usually classified as portable. Usually these machines are designed to make straight-line cuts or bevels. For this purpose, they operate on a track supplied with the machine. These machines are usually limited to operations on material up to 10 in. thick. By means of a radius rod, these machines can be used for cutting circles or operating directly on the steel plate. In an emergency simple, irregular shapes can be cut by hand-guiding the machine. Stationary cutting machines are particularly adapted to operations where the same pattern or design is to be cut repeatedly. Devices are available so that several blowpipes can be mounted on the same machine, and a number of parts of the same shape can be cut simultaneously. In any stationary shape-cutting machine, it is necessary to provide for motion in two directions at right angles to each other. All stationary shape-cutting machines are equipped with a tracing device, driven by a variable-speed motor and guided along the outline of the shape to be cut. There are three methods of guiding the blowpipe when using the stationary cutting machine. They are the line tracer, the strip templet, and the magnetic templet In line tracing, the tracing head is manually guided by the operator along the outline of the part The manually guided tracing head is shown by Fig 12-41 The accuracy of the cut depends on the

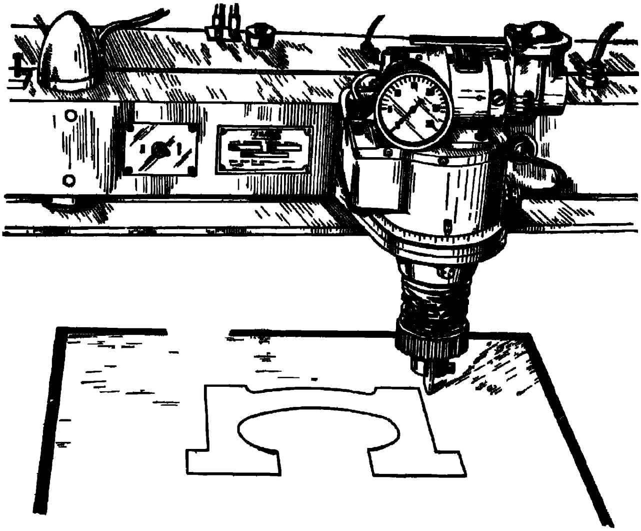

Fig 12-41 A manually guided tracing head

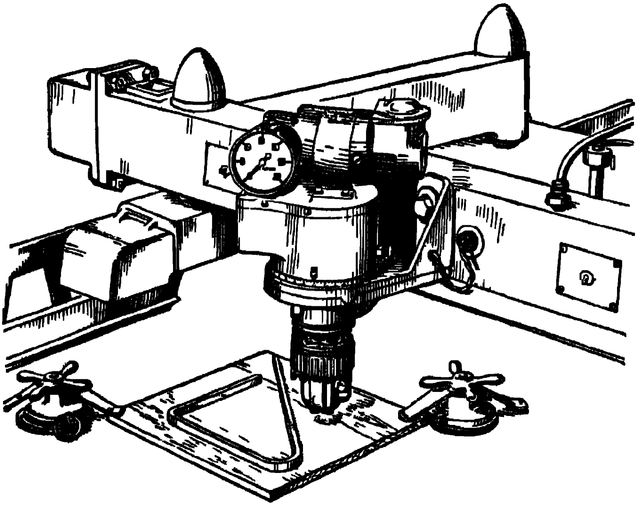

Fig 12-42 A strip templet guided tracing head

skill of the operator For strip-templet guiding, the templet is usually made of a $\frac{1}{4}$ in strip of aluminum The strips are bent to the outline of the part and firmly attached to a sheet metal or composition board base as shown by Fig 12-42 Such templets must be laid out carefully, but they can be used for making hundreds of successive cuts The tracers usually consist of knurled rollers operating on the sides of the templet A magnetic templet makes use of a magnetized knurled-roller that operates on the edge of a templet cut from steel plate about ½ in thick Templet and magnetic tracing head are shown by Fig 12-43

The Oxygen Lance The oxygen lance differs from the cutting blowpipe in that there is no heating flame to maintain the material being cut at the kindling temperature The oxygen lance is essentially a black iron pipe connected to a hose from a regulated supply of oxygen Once the cutting has started, the pipe itself becomes the fuel that burns and furnishes the heat necessary to keep the cut going The oxygen lance is used for rough-cutting heavy sections or for piercing holes in thick metal for the start of an oxygen cut

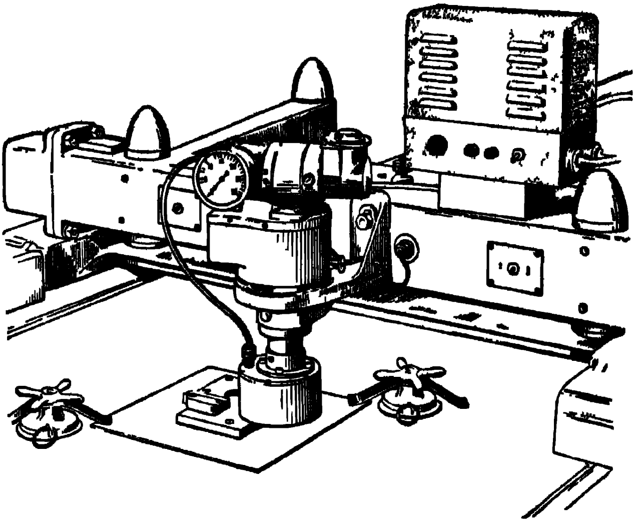

FIG 12-43 A magnetic templet guides the welding head

Preparations for Cutting. The work should be level on the worktable and so positioned that the piece can be cut properly at all points without cutting the work support The relative positions of templet and work can be checked in advance by manually moving the machine over the templet

Dirt, rust, paint, or scale should be removed from the surface before the cutting begins For precision cutting, a flame-descaling operation sometimes precedes the cutting itself

Manual Oxygen-cutting Operations. In addition to the usual precautions in regard to the fire hazards of hot slag and sparks, the operator should protect himself by wearing gloves, a hat, and welding goggles

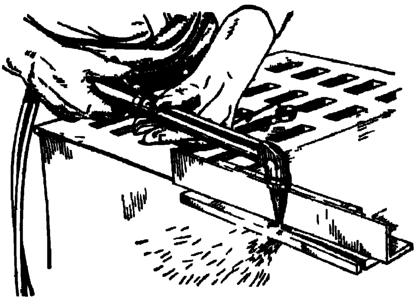

FIG 12-44 A piece of angle iron serves as a guide in making a manual cut

Most manual cuts are made freehand, however, when it is necessary to improve the accuracy, some sort of guide may be used A steel bar or a piece of angle iron will serve to maintain the correct distance above the plate and also to ensure giving a reasonably straight line Such a guide in use is shown by Fig 12-44 The technique of beveling parts for welding is similar to that for straight-line oxygen cutting In selecting the size of nozzle to be used, the metal should be measured along the bevel. The use of a piece of angle iron or other guide helps to make a straight bevel.

Circles and Irregular Shapes. Freehand cutting of circles and irregular shapes is done only when it is necessary to "rough out" a single piece. Circle-cutting attachments usually consist of a short rod with a clamp on one end that fits over the blowpipe head and an adjustable center point.

Piercing Holes. In piercing a hole in steel plate, the preheat flames are held about 1/32 in. above the spot where the hole is to be started. When the surface just begins to melt, the nozzle is raised slightly, and the cutting oxygen lever is slowly depressed. The blowpipe is moved slightly to one side and moved in a small spiral motion as the cutting action starts. When the cut has pierced all the way through the plate, the blowpipe should be lowered so that the tips of the preheat flames are about 1/16 in. above the plates, and the cut continued with a spiral motion until the desired diameter hole has been obtained.

Machine-cutting Low-carbon Steel. Mechanically holding and guiding the blowpipe over the work has many advantages over manual cutting, such as better workmanship and greater accuracy and efficiency. Cutting with straight-line cutting machines is even simpler than manual straight-line cutting. Also, many of the principles of this type of operation apply to other forms of machine cutting. The type of nozzle should be selected according to the quality of cut desired and the size of nozzle should be selected according to the thickness of metal to be cut.

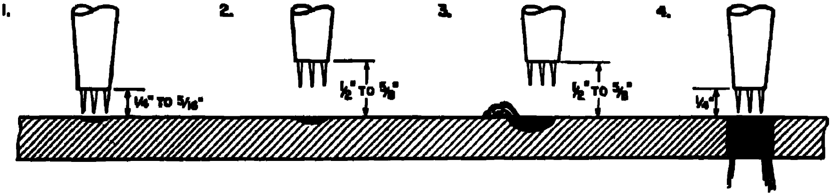

FIG. 12-45. Procedure for starting a machine cut.

Starting the Cut. The lighted blowpipe should be positioned so that the flames fall on the surface of the plate near the edge, with the tips of the inner cone about 1/32 in. away from the surface, shown by Fig. 12-45. When the metal is ready to melt, the nozzle should be quickly moved off the plate so that the center line of the nozzle is about 1/8 in. from the edge. At the same time the cutting oxygen should be turned on and the machine started. This method is generally termed a "flying start" and can be used successfully on thicknesses up to 6 in. or greater with practice.

A simple method of checking the smoothness of the cutting stream is to light the preheat flames, adjust them to neutral, and open the cutting valve. The stream of cutting oxygen can be clearly seen through the envelope of the flame and should be straight and true with a uniform diameter. The operator should check this before starting every cut.

Appearance of the Cut. In a good cut, the surface will be smooth and square, the drag lines will be vertical, and barely visible, the edges will be sharp and straight and any oxide present will be easy to remove.

A cut surface in which the drag lines are straight up and down is called a "drop cut." In straight-line cutting where economy as well as quality is to be considered, the speed of the machine may be increased so that less oxygen and acetylene will be consumed for a given length of cut. In general, cuts having a 10 per cent drag are satisfactory for average run of shop work and are considered standard as to quality.

Shape Cutting. The principles of cutting irregular shapes are the same as for straight-line cutting, with one important exception. Speeds and pressures must be adjusted for minimum drag, otherwise the contour on the bottom of the cut will come out differently from that on top. All shape-cutting machines require some sort of a guiding templet.

Circle Cutting. Nearly all oxygen cutting machines can be adapted to circle cutting. The straight-line machines usually use a radius rod with an adjustable center point. The shape-cutting machines can use either a circular templet of the proper size or a circle-cutting attachment. It is usual to make first a short "lead in" cut through the scrap, so as to have the finished cut smooth and unmarred at the starting point. Such cuts are usually started with a pierced hole. This is possible only when the machine is equipped with a racking facility for lateral adjustment. If racking facilities are not provided, the starting hole must be pierced or drilled tangent to the line of cut.

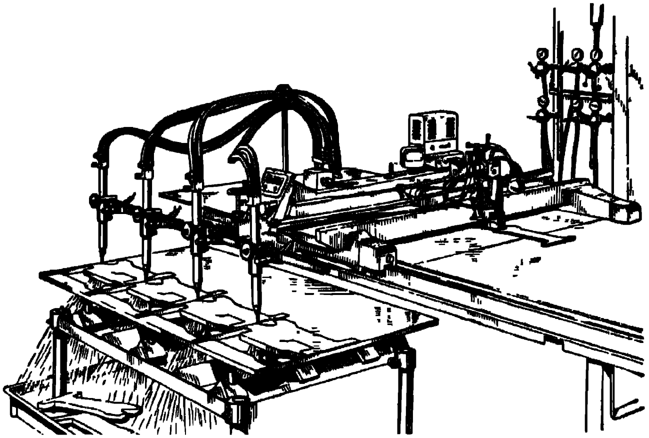

Fig. 12-46. Cutting identical parts with four blowpipes mounted on one machine.

Multiple-blowpipe Cutting. Many of the stationary shape-cutting machines are provided with means for mounting more than one blowpipe. In this way a number of identical parts can be cut at one time. This type of installation is shown by Fig. 12-46. Although only a single templet is required to guide the machine, consideration should be given to laying out the work and to reversing or reorienting the templet so as to produce a minimum of scrap.

Stack Cutting. When relatively thin plates are to be cut, the productive capacity of the machine may be increased many times over that obtained with multiple blow-pipes by piling the thin sheets one on top of the other, firmly clamping together and then cutting as a single piece of heavy material. Stacks with an over-all thickness not greater than 2 in. can be cut with an edge tolerance of $\frac{1}{32}$ in., while stacks having 2 to 4 in. thickness over-all, can be cut with an edge tolerance of $\frac{1}{16}$ in. Obviously, the thickness of the stacks must tie in with the economics of the individual application.

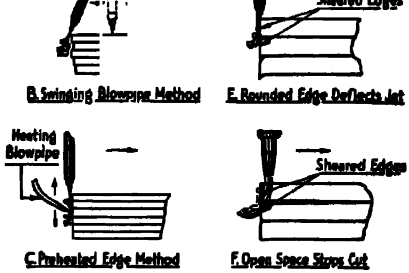

Fig. 12-47. Methods of starting the cut on stacked materials.

Starting the Cut. Starting the cut on stacked plates is the most important part of the operating technique. A faulty start usually damages the edge of several plates and makes a second start extremely difficult. To ensure against mishaps, several methods of starting have been devised as shown by Fig. 12-47, the recommended methods are shown at *A* and *C* but the methods in *B* and *D* are considered poor practice.

Plate-edge Preparation. At one time this work was done by using a single cutting nozzle and making individual cuts. The recently developed rip-and-trim method indicates the possiblity of increasing the speeds and reducing the costs of cutting while still maintaining the accuracy. This method employs two blowpipes: the first of which does the actual cutting, the second, when properly placed, follows and smooths up the cut. The speed of cutting ½-in. plate can be increased by 100 per cent with only about 10 per cent increase in cutting-oxygen consumption.

Multiface Cutting. By using two or more cutting nozzles, plates can be prepared for welding with a single bevel and nose, a double bevel, or a double bevel and nose. The success of this method depends on the positioning of the different nozzles in a manner so that one jet will not interfere with another and also so that the proper heat balance between the zones is maintained. Owing to the fact that the plate surface may be somewhat uneven with respect to the cutting machine, devices have been made to float the blowpipes on the plate surface so that the distance between nozzles and plate is automatically maintained constant.

SPECIAL CUTTING TECHNIQUES

The recently developed powder-cutting process makes it possible to cut cast iron, oxidation-resistant steels and nonferrous alloys with the results equivalent to those obtained in cutting low-carbon steels. In the oxygen cutting of stainless steels, the chromium immediately forms a highly refractory chromium-oxide on the faces of the kerf and prevents further oxidation. Powder cutting provides a means of melting or fluxing out the chromium oxide that has formed. In the reaction zone, the powder is elevated to the ignition temperature by heat from the oxyacetylene preheat flames, where it burns and creates an extremely high temperature reaction. The refractory oxides are continuously removed in a combination melting and fluxing action. The apparatus required for powder cutting consists of a dispenser in which the powder is placed and a means of introducing powder into the reaction zone. This apparatus is shown in operation by Fig. 12-48.

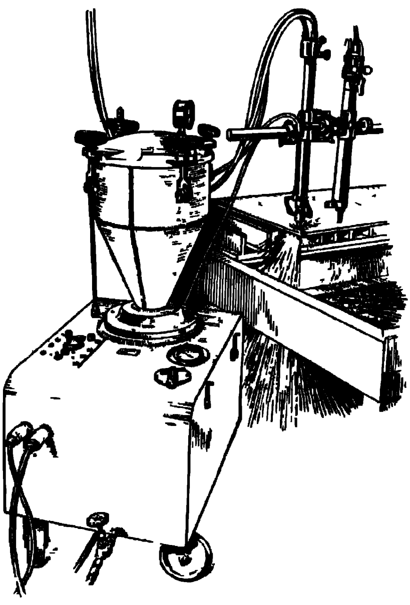

Fig. 12-48. Powder-cutting stainless steel.

Flux Cutting. With materials of low cuttability, the slag formed usually does not flow freely. Frequently, such materials can be cut easier if the slag is made more fluid. This can be done by mixing the slag with slag from materials of high cuttability, or by the addition of certain materials that will produce the same results. This process is known as flux-cutting. A common example of flux-cutting is the hand-feeding of steel welding rod into the cut during the cutting action.

Manual Cutting of Cast Iron. The technique for cutting cast iron differs from that for steel in that a high preheat is required and the cutting nozzle moves back and forth across the line of cut instead of back and forth along the line of cut as for stainless steel.

For determining the nozzle size and the recommended pressures to be used, a certain thickness of cast iron should be considered the equivalent of twice the same thickness of steel. The preheat flames should have an excess of acetylene and the inner cone should be held about 1/4 in. above the surface of the casting. Cast iron can be cut readily by the powder-cutting process.

OXYGEN GOUGING AND MACHINING

In the following applications of gouging and machining, large-volume low-velocity jets of oxygen are used. The purpose is not to cut or pierce but to remove metal from the surface of the piece. Oxygen gouging is a rapid and economical method of forming U-shaped grooves by removing the surface or edge metal from rolled, drawn, forged, or cast steel. Among the principal uses are the progressive gouging of the underside of electric arc welds, spot gouging for the removal of defective weld metal, or tack welds. Mechanized gouging can be used where joint specifications require a U- or J-edge preparation. The flame-gouging blowpipe is mounted on a mechanical device so as to provide a more uniform rate of speed than is possible with manual operation.

Oxygen Machining. With suitable nozzles, the oxygen-cutting process can be used to remove strips or linear areas from the surface of steel stock. The dimensions of the cut taken depend on the size of the cutting-oxygen orifice, the velocity of the cutting oxygen, the rate of travel of the nozzle with respect to the work, and the angle of inclination of the nozzle over the surface of the work.

Effect of Oxygen Cutting on the Cut Edge. Tests have shown that, unless proper precautions are taken, the effect of oxygen cutting on high-carbon steel and certain alloy steels is likely to be detrimental. A thin layer of hardened zone may be produced on the surface when such steels are oxygen-cut at room temperature. This brittle condition, however, is readily overcome by proper heat-treatment. If the high-carbon or alloy steels are preheated to a temperature of about 500 or 600°F before oxygen-cutting, cracking will not occur. Preheating should not be carried too far, as this may have an adverse metallurgical effect. When preheating is used before oxygen-cutting, the majority of steels do not require postheating.

Flame Softening. Flame softening employs a multiple-flame oxyacetylene head that is manipulated about the cutting zone to effect the desired heat-treatment. Flame softening furnishes a rapid and economical means of preventing or eliminating the hardening of higher carbon and alloy steels caused by flame cutting.

INDUSTRIAL-PLANT POWER DISTRIBUTION AND LIGHTING

BY KENNARD PINDER

Fellow, AIEE, Senior Electrical Engineer, E. I. du Pont de Nemours & Co., Inc.

PART 1. INDUSTRIAL-PLANT POWER DISTRIBUTION

Introduction

The production and utilization of electric power has had a very great influence in shaping the present social structure. The introduction of mechanical power brought a centralization of industry near the source of its raw material and power. As mechanical power does not lend itself readily to transmission of power over long distances with good economy, workers found it necessary to congregate in large numbers at the source of power with the result that the older industrial plants find themselves in congested areas with high land costs and taxes and labor difficulties.

Electricity has grown to be the most important form of power. It has been said that the nation which puts in the hands of its people the most abundant supply of electricity will have the highest standard of living. Owing to its flexibility and economy in industrial application and its transmission from the central generating station to the worker, electrical energy permits industry to decentralize and enjoy the advantages of abundant power. Large industries and certain types of process industries sometimes find it profitable to generate their own power, but a large percentage of industrial plants are supplied through a utility company's system with its central electrical generating stations and its radiating network of transmission and distribution lines, substations, and secondary feeders.

Modern industrial executives have come to the realization that their power plant or purchased-power substation and the associated electrical distribution system and power-utilization equipment is an important part of their manufacturing plant. One essential and important difference exists between other production departments and the electrical department. Electrical power, whether the product of the plant power plant or a utility service, is not completed until the instant it is needed, and then only in quantities exactly equal to the instantaneous demand. There is no simple way to warehouse an extra supply of kilowatthours against some future period of extraordinary demand. For this reason the industrial-plant electrical system, in general, must function as a unit and not as a collection of individual pieces of equipment. This statement is significant, as it governs the method of treatment of the subject in this section. Industrial electrical engineering, as construed here, does not include the theory and design of a generator, transformer, motor, or control equipment, but rather the selection of a manufacturer's product with a specific service in mind. There are many excellent textbooks, handbooks, and other technical literature covering the theory of design and operation of electrical equipment.

Almost all industrial plants are tailor-made, and their layout is usually the work of many engineers, designers, draftsmen, operators, etc. One of the principal functions in the design involves industrial electrical engineering, which may be defined as the art of selecting and arranging the necessary electrical equipment and wiring so that (1) a maximum of return will result from a minimum of expenditures over the working life of the plant, and (2) the operation of the completed plant will be such as to provide an economical, reliable, safe, and continuous service.

In weighing the relative merits of one arrangement of electrical equipment and wiring versus another, two items must be considered: (1) that all engineering problems, when solved, are in effect compromises—some desirable characteristics may have to be sacrificed in order to gain something else more desirable at the moment; and (2) most important, the ever-present economic problem goes hand in hand with every engineering problem. Economic justification is the principal factor governing the choice of equipment and the type of electrical layout. Construction costs have risen sharply in the last few years, the greatest increase being in the direct field labor. It is therefore very important to consider and evaluate new design and construction techniques with a view toward improving reliability and reducing costs at the same time.

The subject of "industrial-plant power distribution and lighting" is so large and the factors involved are so variable that it is possible only to cover the major items in a general manner. The scope of the work involved in the design, operation, and maintenance of the electrical system and equipment of an industrial plant is shown in Fig. 13-1.

There are many factors which govern the application of sound engineering principles and procedures in the design of the electrical system. Table 13-1 gives a list of the main factors involved and indicates the type of information that must be assembled preliminary to the design if the electrical system is to prove entirely adequate for the present and reasonably adequate for the future.

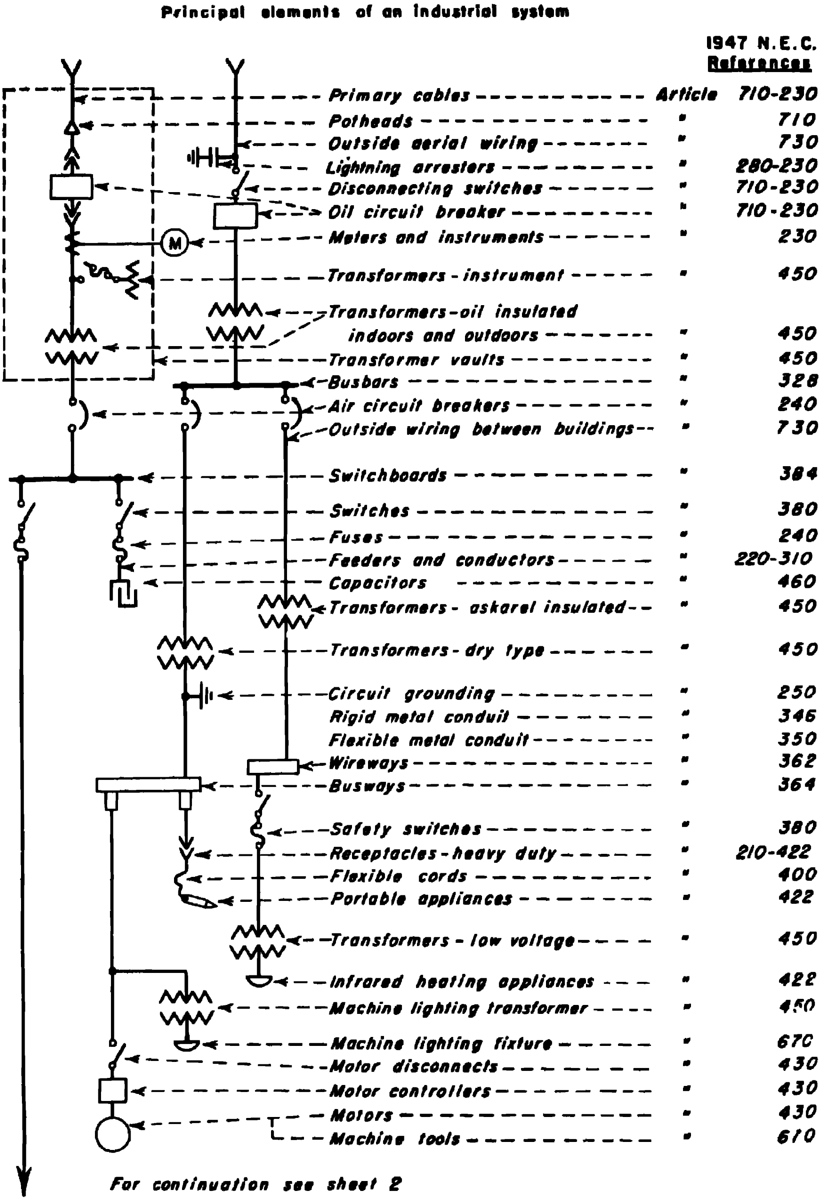
Table 13-1. Factors Governing the Design of the Electrical System for Industrial Plants

1 Character of the plant
    a Kind of product manufactured and physical arrangement and layout of plant
    b Process or material flow diagram showing the magnitude and location of the principal power-consuming equipment
    c Areas where standard type electrical equipment and construction may be used
    d Areas where dripproof, vaporproof, or explosion (vapor or dust) resisting equipment and construction are required
    e. Time allowed for design construction, and procuring materials
2 Size and characteristics of the load
    a. Total connected load—lighting, power, heating, etc.
    b. Probable future load changes and increase in load indicating approximate time when changes and additional capacity are anticipated
    c Maximum kw or kva demand
    d. Power factor and load factor of load
    e. Space available for locating lines, transformers, switchgear, controllers, etc.
3 Type of power supply to plant
    a Is power to be generated locally or purchased
    b If purchased, data are necessary on available power supply, including number and type of primary feeders, their voltage and kva ratings and short-circuit kva which can be delivered over each circuit when each is faulted at plant
4 Service requirements
    a. Importance and degree of reliability required
    b What processes in the plant must be kept operating. (This is where a power failure would ruin the product or create hazards of explosion, dangers to workmen, etc)
    c. If interruptions can be permitted to entire plant, or various types of operations, what is the maximum length of time that may elapse before the reestablishment of service?
5 Technical ability of the operating and maintenance department
    a. Large plants. May be economically staffed with men possessing adequate technical ability and maintenance and operating experience
    b. Small plants. May be necessary to consider operation by persons having scant technical knowledge and possibly but little practical experience

Fundamentals of Industrial-plant Wiring

Electric power is essential for modern industrial-plant operation. The larger the plant, the more significant becomes the selection of the wiring system to supply the energy to the machine tools, process-equipment drives and control, and the plant lighting; but, regardless of the size of the electric load, the problem requires simultaneous recognition of all the items that make up the entire electrical system from the point of entrance of the power-company service or the plant generating powerhouse to the terminals of the utilization devices.

The design of industrial-plant wiring depends primarily upon two basic factors:



Principal elements of an industrial system

Fig. 13-1*b*. Industrial-plant distribution system with code references. Sheet 2.

1. Cost factor—investment, maintenance, and operating costs. This item is greatly affected by the relation of the electrical work to both the physical plant layout and the process-equipment design.
2. Operating factor—service reliability, safety, voltage regulation, working lines energized, joint use of pole lines for power, telephone, and communication circuits, etc.

The analysis of the problem is complicated by the fact that many kinds of electrical equipment, various plant layouts, and arrangements of process equipment have to be considered. The major electrical items encountered in most types of industrial plants are listed below:

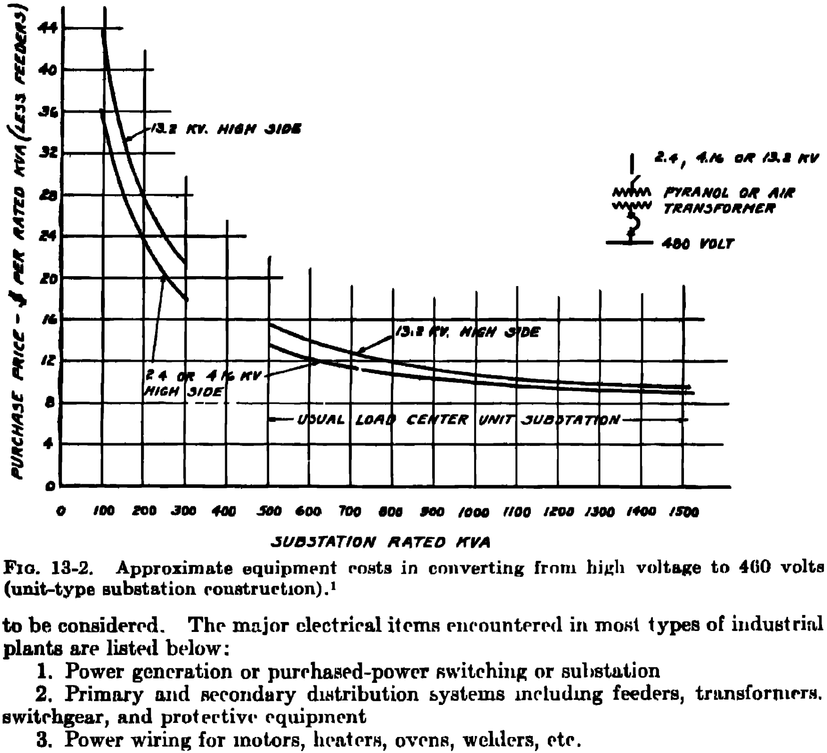

FIG. 13-2. Approximate equipment costs in converting from high voltage to 460 volts (unit-type substation construction).[1]

1. Power generation or purchased-power switching or substation
2. Primary and secondary distribution systems including feeders, transformers, switchgear, and protective equipment
3. Power wiring for motors, heaters, ovens, welders, etc.
4. Lighting equipment, feeders, and branch wiring circuits
5. Electrical and electronic control and instrumentation systems
6. Communication equipment and wiring (public telephone, paging, intercommunication, etc.)
7. Auxiliary systems (fire alarm, electric clock, burglar alarm, etc.)
8. Special items peculiar to process, such as welding, batteries, and rectifiers, electroplating apparatus, elevators and industrial trucks, conveyors, cranes and hoists, ventilation and air conditioning, etc.
9. Yard, roadway, and protective lighting equipment, feeder wiring, and control circuits

In designing electrical distribution systems for industrial plants, major savings can be effected by following certain fundamentals The three major factors influencing the over-all distribution costs are

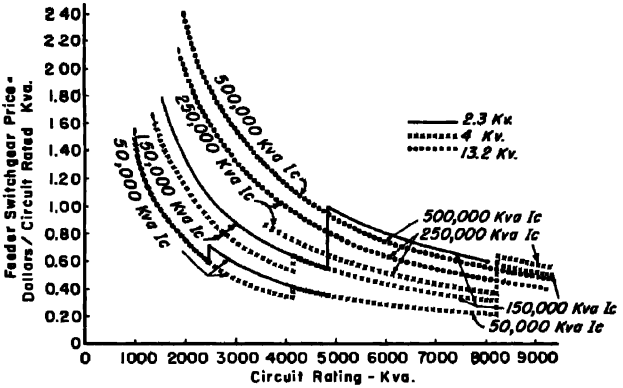
1. High-voltage lines
2. The substation or substations
3. Low-voltage lines

How these three factors vary for specified conditions is shown in Fig. 13-2, Fig

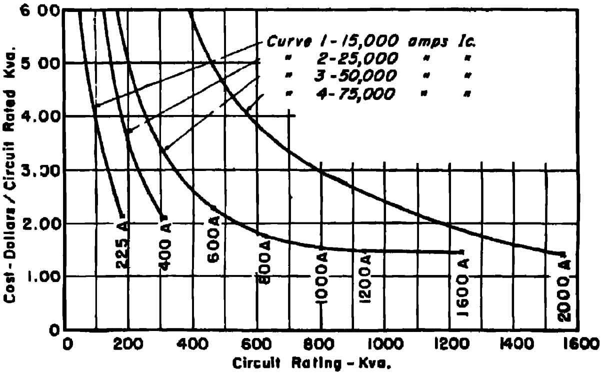
---

[1] Superior numbers refer to entries listed under References on p. 959.

13-3, and Fig. 13-4. Figure 13-2 shows that, from 500-kva capacity to 1,500-kva capacity, the substation costs are about the same per kva, regardless of individual substation size. Figure 13-3 shows how the feeder switchgear costs are influenced by the circuit kva rating, the required interrupting and momentary current in carrying capacity, and by the operating voltage. This figure presents a summary of feeders—switchgear-equipment device in terms of dollars per circuit-rated kva as a function of circuit-rated kva. In Fig. 13-4 the investment costs for feeders are defined



Metal-Clad Primary Switchgear Feeder Equipment Costs



460 Volt Feeder Switchgear Equipment Costs

Fig. 13-3. Metal-clad switchgear equipment costs.

in terms of dollars per kva per 1,000 ft as a function of unit circuit kva rating at nominal voltages of 460, 2,400, 4,160 and 13,800.

From an examination of these figures the following conclusions may be drawn:

1. Except in the smaller sizes the cost of power-conversion equipment is approximately the same per kva regardless of individual substation size. If this is assumed in any study of costs, the problem becomes much easier, as there remain only two variables—the high-voltage lines and the low-voltage lines. When the problem has been analyzed in terms of two variables, the other variables such as transformer costs, switchgear costs, losses, etc., may be brought in, one by one, to see how each will modify the answer obtained at the first trial.

2. Increasing the substation size increases the length and cost of the low-voltage lines. Decreasing the substation size increases the length and cost of the high-voltage

lines. Starting with a large substation, it is possible to determine quickly whether the high-voltage-line costs increase faster than the low-voltage line decreases. If they increase and decrease the same amount, the determining factor is the substation.

3. If the high-voltage lines are underground, they will increase much faster than overhead low-voltage lines decrease and will definitely favor the larger substation. Likewise, if we assume that the low-voltage lines are underground, we get the opposite result, *viz.*, the low-voltage lines decrease much faster than the high-voltage lines increase. What tends to increase the low-voltage-line cost favors the small substation, and what tends to increase the high-voltage-line cost favors the large substation.

4. If we assume that both high- and low-voltage lines are underground, we will find that the small difference which originally favored the small substation will turn out to be a more substantial saving for the small substation. Because of the greater length of low-voltage lines, the cost to put them underground favors the small substation even though the high-voltage lines are underground.

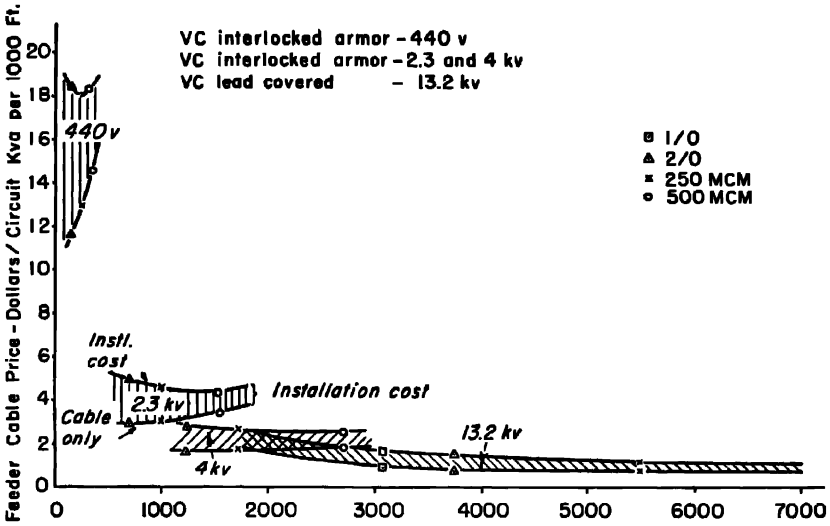


FIG. 13-4. Approximate cost of power-feeder cables.[1]

5. With respect to load density, a high density means shorter lines for both high-voltage and low-voltage lines. The higher the density, the more the substation costs alone control the economics. The lighter the density, the more the lines control the economies, with the substation capacity being larger at higher densities than at lower densities.

From the above, it will be noted that much can be done in controlling the economics of industrial power and its distribution by giving consideration to circuit arrangement. Major savings can be effected by applying the following basic rules to plant layout:

1. Cover as much distance with high voltage and as little with low voltage as possible, consistent with plant layout and process requirements. Distribute power at the highest practical voltage.

The amount of conductor required to transmit 1,000 kva at voltages ranging from 460 to 13,200 volts varies from 100 per cent for 460 volts to 1.8 per cent at 13,200 volts. This difference becomes a more staggering differential when it is stated that it requires one No. 6 copper cable per phase at 13,200 volts and six 250,000-cir mil cables per phase at 460 volts to transmit 1,000 kva over a comparable distance.

By selecting the highest practical primary (2.4 to 13.2 kv) and secondary (460 volts and below) voltages, a large percentage of copper or aluminum required for feeder cables can be saved. A practical example follows:

To carry a 150-kva load three phase at 208 volts requires three 500,000-cir mil copper conductors weighing 4.6 lb per ft; at 230 volts, three 400,000-cir mil copper conductors weighing 3.8 lb per ft; at 460 volts, three 2/0 copper conductors weighing 1.2 lb per ft.

2. Locate the substation as close as practical to the "load center" of the area. Please note the word "practical." There are many installations made to serve equipment in hazardous locations such as carbide generators, paint mixing, solvent vapors, oil and gasoline storage, and explosive dusts. It would be imprudent to locate any standard switchgear equipment within the hazardous area.

However, in systems with the substations located outside the process area, 60 to 75 per cent of the total feeder conductors by weight is required for low-voltage distribution. By locating the substation at the center of the load, the low-voltage feeder lengths are reduced an average of 33 per cent, and the total conductor requirements are reduced about 15 to 40 per cent.

Locating the substation at the center of the load area often means locating it in the working area. Compact, enclosed substation equipment of the air-cooled type or equipment utilizing askeral liquid (noninflammable) may be installed in nonhazardous working areas without vaults. The most practical method is to locate these units on balconies, along building column centers, or in similar areas of minimum value as working space.

3. Use substations of reasonable size. By using, tor example, four small substations rather than one large substation to serve a square load area, one-half the low-voltage feeder conductors can be saved. There is, however, a limit to the desirable reductions in ratings. As the size is reduced, more material is required for high-voltage feeders, and less efficient use is made of the material for constructing smaller substations.

In general, the optimum rating of a three-phase substation with 460-volt secondaries will be from 500 to 1,000 kva; for 208/120- or 230-volt secondaries, 300 to 500 kva.

4. Use cable with high-temperature insulation. The use of high-temperature insulation on wiring for main power and lighting feeders will permit a higher current rating for the same size of conductors. The smaller size wire for a certain current rating also permits the use of smaller conduits. However, in industrial-plant wiring, it is almost always desirable and economical to install services and main feeder conductors of larger sizes than are required for the initial load. If 75°C insulation is installed with initial currents according to the 60°C insulation, advantage may be taken of the difference in rating for any load increase.

5. Use as simple an electrical distribution scheme as possible consistent with justifiable service reliability and required maintenance practices. In general, it is axiomatic that, the more complicated the distribution system, the more feeder material is required to carry a given kilovolt-ampere load. It is often said that extra complication is necessary to give satisfactory service reliability. To accomplish this, we provide means for isolating possible cases of trouble, dual supply circuits, or complicated secondary networks. The processes should be analyzed to develop which building or piece of apparatus is critical and build the system to suit. It is obvious that it is seldom that the whole plant requires an uninterrupted supply of power.

6. Select the proper equipment. Construction costs have risen sharply in the last few years, the greatest increase being in direct field labor. It has been proved that, substations designed piecemeal with individual pieces of equipment, individual motor starters, safety switches, control panels, etc., ultimately cost more than factory-assembled metal-enclosed equipment. The latter results in lower first cost when properly considered with regard to

a. Substantial reduction of initial layout-engineering time

b. Reduced installation time

c. Use of manufacturers' lower priced "repetitive-manufacture" units which reflect direct saving through volume production

Another item that must be considered in considering costs of substations is the use of auxiliary cooling equipment in the form of forced air on medium-size banks and forced oil in combination with forced air on large transformers. A second item that saves material and reduces costs, except in the smaller distribution transformers, is the use of three-phase instead of three single-phase transformers for supplying three-phase loads.

Electrical Distribution Systems

The local distribution system serves the industrial plant in very much the same manner as the combined transmission and distribution systems serve the utility company. Industrial plants offer a big variation in providing a distribution system to distribute the output from the local generating station, from the purchased-power lines, or from these sources, where paralleled, to the various individual loads throughout the plant

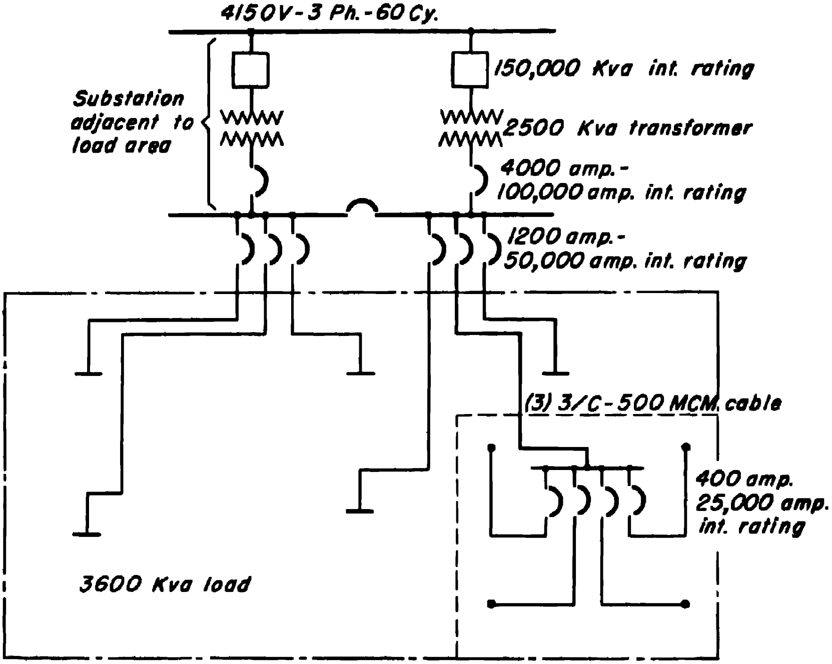

FIG. 13-5. Conventional-type distribution system (multiple low-voltage feeders).

What form of distribution system checks up as best for a plant depends entirely on how much value can be attached to dependability and flexibility in the system. For example, if power is to be used in the manufacture of a product, such as that of an automobile, where the design is changed frequently and extensively, a flexible, easily changed system is indicated. Where continuity of service is essential, such as some chemical processes where a batch could be ruined by a power failure, an extra-dependable system should be used.

Up until a few years ago, the electrical system in most industrial plants consisted of a single large-capacity substation which stepped down the supply voltage to the low-voltage utilization voltage, with 2,300-volt systems being the highest industrial-distribution voltage even for the larger plants Such an arrangement, commonly called the "conventional" type of distribution, is shown in Fig. 13-5. The distribution from the main switchboard involves large low-voltage feeder conductors which are very expensive to install and result in heavy transmission losses. Most plants today use higher voltage distribution systems (4,160, 6,900, 11,500, or 13,200) for supplying transformer banks of adequate size within the load areas "Unit-type substations" are economically employed, particularly where the total plant load is above 500 kva and somewhat uniformly distributed throughout the area The advantages and disadvantages of the "conventional" and "unit-type-substation" distribution systems are given in Table 13-2 The desirable installation and operating features of the unit-substation-type industrial-distribution system are summarized below

Table 13-2. Comparative Performance of Conventional versus Unit-type-substation Distribution Systems

Advantages (+) Disadvantages (−)

Item	Conventional	Unit-type substation
Transformer cost	(+) Less transformer capacity usually is required when a single conventional substation is used Averaging out demand for an entire plant permits taking greater advantage of load factor	(−) Two or more smaller capacity transformers cost more than one large transformer
Secondary breaker costs in small plants (500 kva or less)	No advantage	No advantage
Secondary breaker costs in large plants (over 500 kva)	(−) When conventional single-transformer system is used in large plants high kva rating transformers are required and thus large and expensive secondary breakers are inevitable	(+) Splitting a large load between smaller size transformers permits smaller and less expensive secondary breakers
Cable costs (small area plants)	No advantage	No advantage
Cable costs (large area plants)	(−) Long lengths of low voltage feeders are uneconomical	(+) Short secondary feeders from transformers located at load centers
Efficiency	(−) Higher loss due to longer cables	(+) Fewer losses from shorter secondary feeders
Voltage regulation	(−) Becomes worse the longer the secondary feeders	(+) Good and uniform
Service reliability	(−) Failure of main transformer or fault on main bus affects entire plant load	(+) Failure of any one part does not necessarily mean an interruption of the entire plant load
Interchangeability	(−) Breakers only	(+) Breakers transformers and entire substations can be planned to be interchangeable
Flexibility	(−) Requires entire plant-load interruption when certain changes are in progress	(+) May be designed for high degree of flexibility and permit arrangement changes with minimum service interruption
Expandability	(−) Single transformer limits possible plant additions and load increases	(+) New substation can be readily added when, as and if new load develops

1 They are installed at centers of load demand where cable runs are short

2 Because extensive engineering and planning are not necessary and the equipment is self-contained, little time is required for installation

3 Beginning with small units, substation capacity can be added in small increments as required, saving fixed charges on the unused capacity of larger units or on large substations located away from load centers

4 One cannot always foresee exact factory load conditions, and here the unit substation is a help It can be moved from place to place if changes in load conditions become sufficiently great to require it

5 A number of small unit substations offer a high degree of over-all service reliability Since each serves a relatively small load, outages of any of its elements involve the dropping of a relatively small amount of load

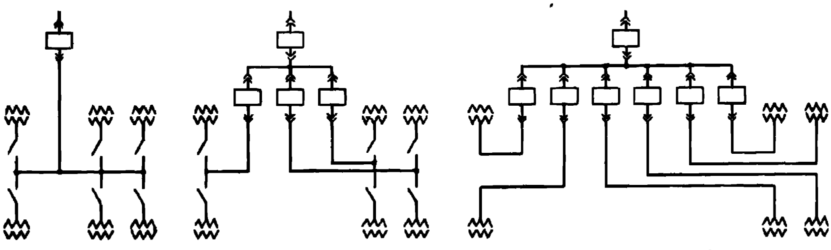
6 Excellent voltage regulation can be obtained by means of the ratio-control equipment on the transformer, ensuring the greatest economy in regulating equipment.

7. The metal enclosure provides a feature particularly desirable in the industrial plant, with the elimination of accidental contact with live parts, the assurance of safety to personnel, and protection to the enclosed equipment.

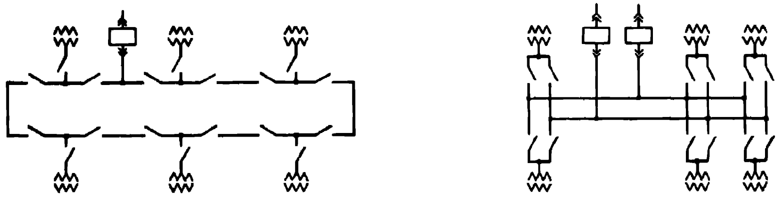
8. Because of standardization of units, additional unit substations can be purchased economically in simple transactions based on definite costs without involved engineering studies, plant layouts, or additional building structures.

There are a large number of plants which are satisfied with a single purchased-power feeder supply, particularly where the feeder is overhead and faults on it can be located and repaired in a relatively short time. The larger plants, or plants where continuity of service is very important, will usually require two or more primary feeders to serve them.

Today, for all plant loads over 500 kva, the unit-type substation construction should be considered and its advantages and disadvantages compared with the conventional-type distribution. Table 13-2 shows such a comparison.



Simple Radial (a) Simple Radial (b) Simple Radial (c)



Single Loop Radial (d) Primary Selective (Double Radial) (e)

FIG. 13-6. Basic primary voltage-system arrangements.

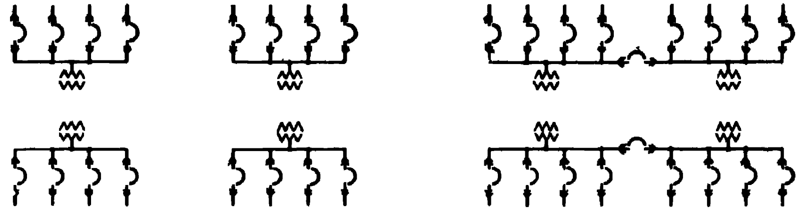
The primary distribution systems in industrial plants have been, in the past, in almost all cases, some form of radial system similar to that shown in Fig. 13-5. Figure 13-6 shows three basic primary voltage-system arrangements, each of which can be used with any type of low-voltage system.

The simple radial system *a* has one primary-feeder breaker for all transformers. This arrangement is inferior to the conventional-type system in service reliability, since a number of the transformers are connected to the primary feeder, and a fault in the feeder or disconnect switch and trouble in any transformer will result in an outage to the area. This outage may be of long duration since service cannot be restored until the trouble is located and repairs are made. As the breaker must carry the full-load current of all transformers simultaneously, short-circuit current of one transformer will not look so big to *the breaker* if the other transformers are highly loaded, and the breaker may be slow in opening.

The simple radial system *b* shows that, by increasing the number of primary feeders and breakers and connecting only two transformers to each feeder, the extent of the outage can be reduced when a primary-feeder fault occurs. While this represents an increase in cable and breaker expense over the simple radial system *a*, better transformer protection and greater system dependability are obtained. For most plants, this would be a wiser investment than system *a*.

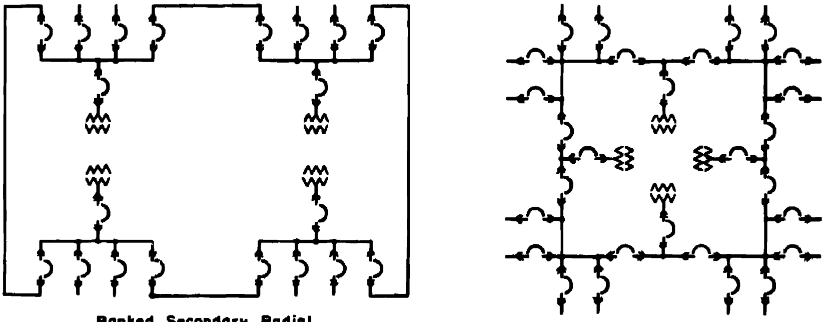
Simple radial system *c* shows an increase in the number of feeders carried to the point where there is only one transformer per primary feeder. This is both the costliest and the most dependable of the three versions of the simple radial high-voltage system. This form of simple radial system will usually be very expensive and can seldom be justified.

The single-loop radial system *d* employs a sectionalized loop controlled by a single primary-feeder breaker. This system requires more primary cable and additional disconnect switches and is only slightly more expensive to install than the simple radial system *a*. The advantages are that (1) transformers and cable difficulties can be deenergized for inspection and repairs without further interruptions to the rest of the system; and (2) regulation and efficiency are improved over the simple radial system.



Conventional Secondary Radial

Secondary Selective Radial



Banked Secondary Radial

Loop Tie Radial

Fig. 13-7. Basic secondary voltage-system arrangements.

The primary selective radial *e* is, in effect, one simple radial system imposed upon another, each having sufficient capacity to carry the essential plant load. The addition of a second primary-feeder breaker and extra primary cable makes this the most reliable and flexible of the three basic high-voltage systems and also the most expensive. Failure of one line means dropping of only half the load, and only for as long as it takes an operator to throw the loads interrupted over to the line still in service. Repairs and changes can be made in one line while the other carries the load. The benefits derived from the reduction in the amount of load dropped when a fault in any section of the primary occurs, plus the quick restoration of the service to all or most of the system, are of considerable importance.

Figure 13-7 shows four basic secondary voltage-system arrangements. Any one of the systems can be used with any one of the high-voltage systems previously considered. These systems are alike in that power is fed to the loads through radial circuits. The chief difference between them lies in the extent to which power is maintained on the low-voltage side of the transformer in case of primary-system failure.

The conventional secondary radial system is the one most commonly used in industrial plants because of its lower cost. While it is essentially a scaled-down, low-voltage version of the conventional primary system, the shortcomings of this system are less serious on the low-voltage side because cable runs are shorter.

However, the conventional secondary radial system has a minimum of dependability. If the transformer fails in any distribution unit, that entire unit must be taken out of service until repair or replacement can be made. To overcome this disadvantage, tie connections can be made between individual units. Tie connections can group the unit into pairs resulting in a secondary selective radial system, or a complete secondary loop can be formed resulting in a banked secondary radial system.

The secondary selective radial system has two load-center units grouped to form a single substation. This secondary system is used mainly with the corresponding primary selective radial system, in which one transformer is fed from one of two lines and the second transformer from the other.

Tie breaker between the units is normally open. The two main breakers and the tie breaker are so interlocked that only two of them can be closed at a time. Each transformer may be large enough to carry either the combined load or only its own load plus emergency load from the other unit. In either case, transformer investment is greater than in previously considered systems. Because the tie breaker is normally operated open, short-circuit currents are no larger than with a conventional radial system.

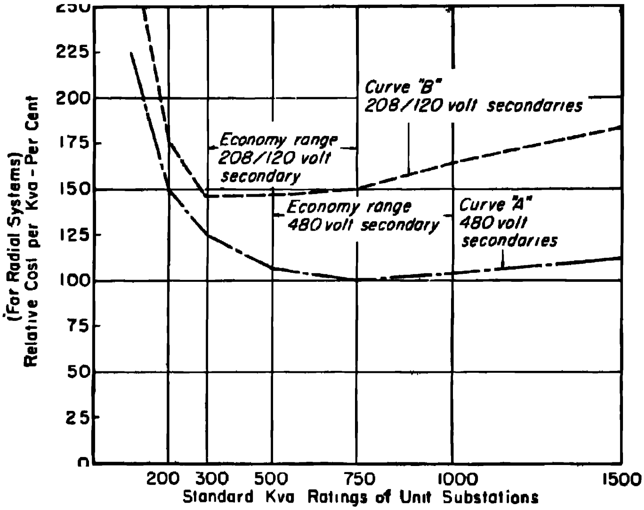


FIG. 13-8. Unit substation sized within "economic range."

Cost of this system is slightly higher than that of the conventional secondary radial system. Dependability is much greater. This system can be used in a modified form to pick up the load supplied from a single transformer substation by extending the tie circuit and connecting it to the substations through tie-line breakers.

The banked secondary radial system is a form of secondary network scheme. Power is supplied to the load centers throughout the plant over two or more primary feeders. Each primary feeder and its associated transformers function as a unit, and the network must be so designed that the entire plant can be carried when one primary feeder and its associated transformers are out of service. This system is not justified for most small plants, but it appears to offer some economic promise where there are two or more primary feeders available for serving the plant and where the load density in the plant and the total plant load are large.

A tie connection may be a solid connection but should have breakers at each end, as shown above. Should one unit be overloaded, power will be fed automatically from the adjacent unit; more efficient transformer loading is obtained.

The tie connection increases the short-circuit currents possible on feeder circuits so that larger feeder breakers may be required.

The so-called "secondary network" for industrial plants is a banked secondary radial system where the transformer secondary breaker has been replaced by a network protector. Flexibility, regulation, and reliability are unchanged, but the cost is increased considerably.

The loaded-tie radial system differs from the banked secondary radial system in the location of the feeder breakers. In the banked secondary system the tie cables must be capable of carrying from 60 to 70 per cent of the current from one transformer bank. On a balanced system little current flows through these tie cables except in emergencies.

Here all the power flows through the tie cables, thus requiring them to be larger, but there is a net saving in copper because the tie breakers are tapped off the tie as near as possible to the load. This shortening of the cable from feeder breaker to load not only saves copper and reduces installation cost but also improves regulation and efficiency. The system has better characteristics in emergency operation than the banked secondary radial system.

Figure 13-8 shows the relative cost of various substation sizes for 460-volt and 208/120-volt secondary distribution with the economical range of capacity noted.

Table 13-3 shows the comparative performance of various groupings of basic primary and secondary voltage-system arrangements.

Table 13-3. Comparative Performance of Distribution Systems

Item, based on 10 va/sq ft and plant building area of 750 ft (length) by 500 ft (width)	Unit-type-substation arrangements					Conventional multiple low-voltage feeders

Voltage of the Primary Distribution System

The distribution-system voltage or voltages is one of the first factors to be considered in laying out the distribution system in an industrial plant. The distribution-system voltage, or voltages, is materially affected by the size of the motors or other electrical equipment which are to be operated, the total kva load, the area over which the power is to be distributed, and, to a greater or lesser extent, by the generated or incoming voltage.

With respect to the primary distribution system, if the voltage of the incoming utility lines is 13.2 kv or below (generated power is always within this range), primary distribution at this level will generally be most economical. Higher voltage will be stepped down by a master substation unit before plant primary to local substation units and other high-voltage-utilization equipment.

Satisfactory and convenient distribution must follow standard practice as to frequency, number of phases, and nominal system voltage. Sixty-cycle systems predominate in this country and are superseding twenty-five-cycle systems for practically all applications with the exception of heavy-duty steel-mill work. In general, three-phase supply is most desirable. This leaves the question as to which primary voltage is most economical.

The fact that standard voltages are in steps, *i.e.*, 2,400, 4,160, 6,900, 11,500, or 13,200, indicates that the problem is one of comparing the cost for any one condition with that for the others, rather than attempting to determine a theoretically most economical voltage. A general cost equation may be written for each voltage classification as follows:

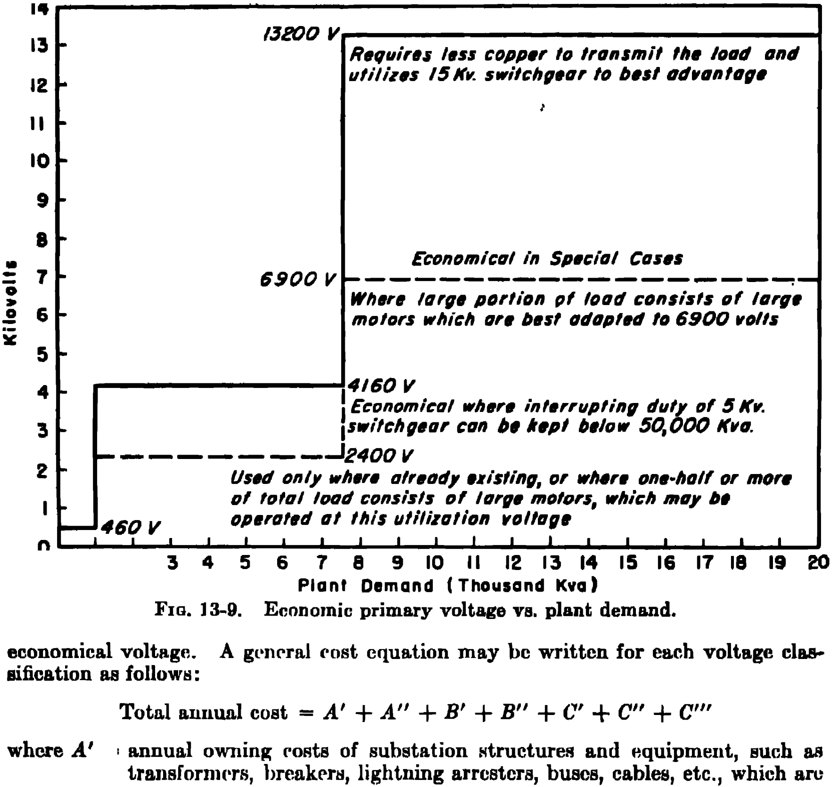

Fig. 13-9. Economic primary voltage vs. plant demand.

$$\text{Total annual cost} = A' + A'' + B' + B'' + C' + C'' + C'''$$

where A' = annual owning costs of substation structures and equipment, such as transformers, breakers, lightning arresters, buses, cables, etc., which are affected by the voltage

A'' = annual costs of energy losses in substation which vary with the voltage

B' = annual owning costs of primary lines in place with consideration given to conductor size, voltage drop, insulators, pole-line construction, etc.

B'' = annual costs of energy losses on primary lines

C' = annual owning cost of distribution transformers in place

C'' = annual cost of core losses on distribution transformers

C''' = annual cost of copper losses on distribution transformers

The above factors show that the choice of voltage depends not only upon the total kva to be supplied but also upon the area over which it is distributed.

A study of the distribution-systems costs for medium-sized plants is summarized in Fig. 13-9. In nearly all cases, the 4,160-volt supply is more economical than the 2,400-volt supply. This is true because the 5-kv switchgear is used more effectively than at 2.4 kv; smaller cables are required at the higher voltage; and motors of less than 200 hp can be operated at 460 volts (stepped down from 4.16 kv) at a lower over-all investment cost per horsepower than directly at 2.4 kv because of the higher starter and wiring costs for the latter. Also, the extra cost of motors larger than 200 hp rated at 4,000 volts instead of 2,300 volts is less than the saving of 4,160-volt over 2,400-volt transformers and distribution. Comparative curves of investment for industrial power systems and motors and controls are shown in Fig. 13-10.

In general, while the higher voltages offer the double advantage of lower line losses and lighter and cheaper cables leading to each substation, experience proves the practicability of choosing a primary voltage of 4,160 for industrial-plant demands up to 7,500 kva and 13.2 kv for larger plant demands. The terminal apparatus is approximately proportional to the voltage. The line costs, however, vary only moderately with the voltage for a given amount of power to be transmitted.

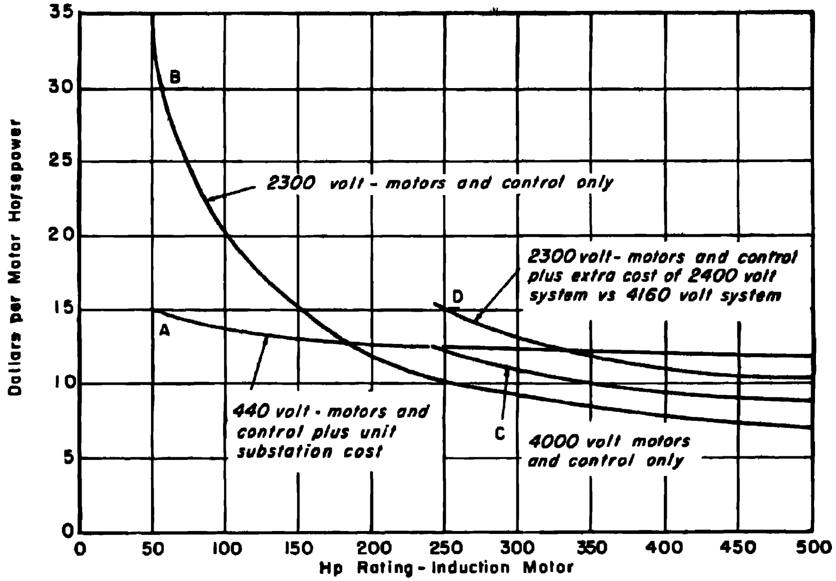

FIG. 13-10. Comparative curves of investment for industrial power systems and motors and controls.[7]

Voltage Best Suited to Utilization Apparatus

Most industrial-plant equipment has a majority of relatively low-rated utilization apparatus, usually not in excess of 25 kw or 25 hp. Economy on feeder and branch wiring, together with controllers and switching, indicates that, in general, the systems shown in Table 13-4 should be used to supply the equipment noted.

For economical location, not only the substation but also the motor control centers, power and lighting panels, and other distribution boards should be located as near as possible to the center of the load. By representing the normal rating of each piece of utilization apparatus as a weight and its distance from a fixed reference or base line as its moment arm, the economical weight of the wiring system can be determined. Locating the load centers as closely as practical to the center of the load results in the most economical layout.

Another of the most important factors to be considered in determining the economical distribution system is the selection of the voltage. The best example of the advantages may be illustrated by considering the factors or constants used to determine the current and wire size for a known load. Figure 13-11 shows the commonly

Table 13-4. Equipment-utilization Voltages

Nominal voltage	Phase	Number of conductors	Equipment
120	1	2	Fractional-horse power motors up to and including ½ hp Heaters, ovens, etc , up to and including 1½ kw Incandescent and fluorescent lighting
208 220	3 and 3	3 3	Motors—¾ to 25 hp—three phase Heaters, ovens, etc , from 2 to 3 kw, single phase at 208 volts or 220 volts Heaters, ovens, etc., from 4 to 50 kw, three phase Fluorescent and mercury lighting Portable power equipment
460	3	3	Motors—¾ to 150 hp Heaters, ovens, etc , from 5 kw up
460/265	3	4	Same as for 460 volts—three phase noted above, plus fluorescent and mercury lighting in industrial-plant areas where the fixtures are mounted at least 8 ft above floor
4,160	3	4	Motors—200 to 4,000 hp (current-limiting fuse protection limit—1,000 hp; larger motors require oil circuit breakers)
6,900	3	3	Motors—above 500 hp
13,800	3	3	Motors—induction, above 800 hp, synchronous, 2,000 hp and larger

used utilization-wiring systems, and Table 13-5 gives a comparison of the essential data which should be considered in determining the best utilization voltage.

The 575-volt power system was formerly used in some sections of this country, but this voltage may now be considered obsolete except for extensions to existing systems. The 575-volt system is slightly more economical than the 460-volt system, but 550-volt utilization equipment is not so readily available as equipment rated at 440 volts. Also, as 600-volt insulated equipment and wiring are used on both systems, the 460-volt system has the greatest safety factor.

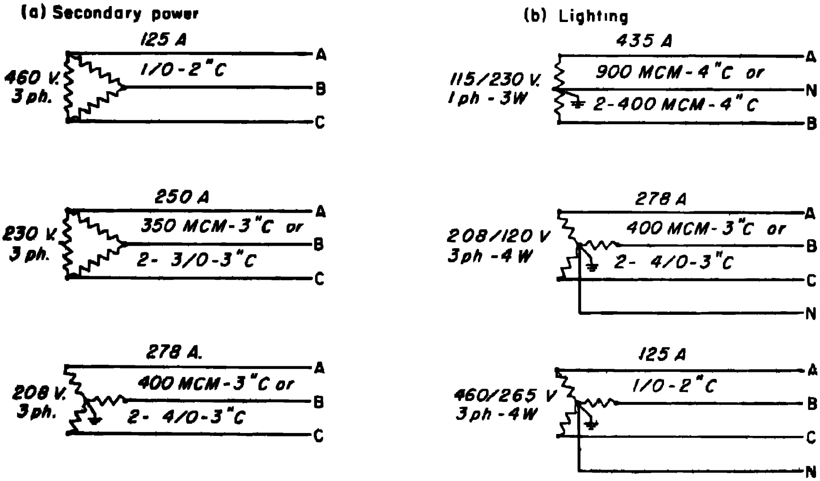

FIG. 13-11. Comparison of wiring systems (100-kva base).

Raising the plant voltage or changing over an existing system cannot usually be justified on a power-savings basis alone. It is a worth-while consideration toward defraying the cost should increased capacity be required. In most cases a change to higher voltage can be accomplished at a lower cost than the installation of heavier feeders should the minimum additional load be 30 to 40 per cent of the existing load.

Table 13-5. Comparison of Various Voltages for Equal Loads

Low-voltage power, three phase

Voltage	460	230	208
Current/kva	1.25	2.50	2.77
Current, per cent	100	200	221.6

115/230-volt base, 1 φ 3 wire base	67	100	27
460/265-volt base, 3 φ 4 wire base	250	375	100

Voltage Variation

Electrical engineers have a very special interest in voltage standardization because all electrical equipment and construction material is designed and manufactured for a definite voltage range. Construction material is rated generally in terms of the maximum voltage for which it should be used. For example, wire insulated for 600 volts may be used on any circuit in which the applied voltage does not exceed 600.

Utilization equipment, such as lamps, motors, electronic tubes, and heating devices, is manufactured for operation on a relatively small variation from the rated voltage of the equipment. Nearly all such equipment is rated at a particular voltage, which must be provided to obtain the designated operating characteristics or to acquire the guaranteed results. However, the manufacturers recognize that there will be voltage variations on the circuits supplying the equipment and so design their products that satisfactory operation will be obtained over a range of voltage which will vary with the equipment. One, two, five, or ten per cent voltage variation may be allowable depending upon the equipment and the use to which it is put.

The light output and life of incandescent lamps vary markedly with the voltage. An increase of 5 per cent (6 volts on a 120-volt system) will increase the light output of an incandescent lamp 18.5 per cent and will decrease the life to about 55 per cent of its rated life. A decrease of 5 per cent in the rated voltage will decrease the light output 16 per cent and will double the rated life.

The characteristics of fluorescent lamps change also with voltage variations but not to such a degree as do the incandescent lamps.

Variations of voltage above and below the design voltage also affect the life of electronic tubes and their operating characteristics at a much higher rate than the fluctuation of the voltage.

The operation characteristics of motors, especially induction motors, change with the voltage. The starting torque of induction motors varies as the square of the voltage. The temperature rise increases with the decrease in rated voltage and decreases with an increase in voltage within certain limits.

For satisfactory operation of industrial electrical apparatus it is important to have and maintain a proper zone of utilization voltage. For further discussion and information on the results of voltage variation upon the operating characteristics of utilization equipment, the reader is referred to AIEE *Miscellaneous Paper* No. 47-157 entitled "Report on Industrial Voltage Requirements" issued in May, 1947.

The electrical engineer designing the wiring system for an industrial plant has no control over the voltage variations of the electricity supply where the supply is received at utilization voltage. Where the electricity supply is received at a voltage higher than the utilization voltage and where transformers are to be installed or where the electricity is generated as a part of the project, the engineer can control the voltage variations by means of voltage regulators and tap changers on the transformers or by voltage regulators on the generators.

From the service switch or from the secondary terminals of the transformers, if they are installed, the fluctuations in voltage *caused by the load* are within the control of the designer of the system. In any circuit, as the load increases, the current and the voltage drop increase in direct proportion. This voltage drop can be controlled within the desired limits by the installation of wires of ample size and by reducing the load on each circuit. For branch circuits, it is desirable generally to limit the wattage rather than to install larger wires. For feeders, ample cross section should be used in the wires to limit the voltage drop in order to obtain the proper voltage at the points of utilization.

The National Electrical Code (Sec. 2202) recommends that the voltage drop in feeders for lighting circuits be limited to 1 per cent and in power circuits to 3 per cent from the service switch, or transformer secondary terminals, to the farthest distribution panel board. Governing authorities may require limitation of voltage drop to other than these figures or may not require in their codes at all the limitation of voltage drop.

The National Electrical Code has limited the current to be carried in each size of wire depending upon the conductor material and the type of installation. These limitations are based upon temperature rise only and have been determined by test. Voltage drop in the circuit does not enter into the determination at all. However, it may be that, for a given current, a No. 14 AWG wire may be used, yet a No. 10 AWG is necessary in order to maintain a low drop in voltage in the circuit

Consider a branch circuit 75 ft in length with a 12-amp load concentrated at the end of the circuit. According to the Code a No. 14 AWG copper wire will satisfy the requirements. The voltage drop in this circuit will be

$$VD = \frac{12 \times 2 \times 75 \times 2.63}{1{,}000} = 4.73 \text{ volts}$$

where 2.63 is the resistance per 1,000 ft of No. 14 wire

A voltage drop of this magnitude is high and generally too high for good operation of electrical equipment. If it is desirable to limit this drop to 2 volts, the wire size should be

$$\text{Wire size} = \frac{11 \times 2 \times 75 \times 12}{2} = 9{,}890 \text{ cir mils}$$

This size is slightly less than a No. 10 AWG copper wire, which is the proper size to use to limit the voltage drop to the desired amount.

The calculation above is based on the following formula:

$$\text{Circular mils} = \frac{R \times L \times I}{VD}$$

where L = length of wire, in feet
a. For single-phase circuits
For d-c circuits
For each leg of a two-phase four-wire circuit } twice the length of the circuit
b. For three-phase circuits 1.73 times the length of circuit
I = current per conductor
VD = allowable or desired drop in voltage in circuit
R = resistance per mil-foot of conductor: for commercial copper wire, 11; for commercial aluminum wire, 17.25

It is recommended that the maximum voltage drop under full-load conditions from the service switch or the distribution transformer (depending upon the installation conditions) to the center load of the farther branch circuit (to the first outlet on the branch circuit if the outlets are reasonably close together) be limited to 3 per cent for lighting circuits and 5 per cent for power circuits. In calculating the voltage drop, the full-load current of lighting circuits should be used and also the summation of the full-load running currents for motors on power circuits. This latter current will be somewhat less than the current required by the Code for the determination of the proper size of wire which includes an additional 25 per cent of the current of the largest motor on the circuit.

If the total drop from service switch to the point of utilization is limited to 3 per cent for lighting circuits and 5 per cent for power circuits and if the drop in the feeders is limited to 1 per cent and 3 per cent as recommended by the National Electrical Code, the voltage drop in branch circuits is then limited to 2 per cent for both types of circuits.

FIG. 13-12. Industrial-plant power and lighting systems.

The figures given above are the maximum drops that should be allowed in any electrical wiring system. It is good practice to limit the drops, especially in the branch circuits, to narrower limits.

Comparison of Methods for Supplying Power and Lighting. Figure 13-12 shows the methods usually used in the new low-voltage distribution systems of industrial plants.

Method *a* shows a layout with separate substations and feeders for lighting and power. This system is usually the highest in first cost and operating cost and requires the largest space.

Method *b* shows a layout with a 208/120-volt substation, or substations, and feeders with power supplied at 208 volts, three phase, three wire, and lighting supplied over a 208/120-volt, three-phase, four-wire system. This system is generally most economical for small compact plants where feeders are not over 100 to 125 ft in length and the motors are small in size.

Method *c* shows a layout of a power substation operating at 460 volts, three phase, with power supplied directly at that voltage and the lighting supplied with 460-volt primary air-cooled transformers with either single-phase or three-phase secondary distribution. The system is particularly advantageous where the power load is three times the size of the lighting load or more. The advantages of this system are (1) the elimination of one complete distribution system and the concentration of substation capacity in a smaller number of larger units and (2) savings due to the reduction of copper in the distribution of lighting load at power voltage because of the greater radius of distribution at the higher voltage.

Method *d* shows a layout with a 460/265-volt substation, or substations, and feeders with power supplied at 460 volts, three phase, three wire, and lighting supplied over a 460/265-volt, three-phase, four-wire system. The 460/265-volt system is limited to light sources of 85-watt fluorescent, 40-watt 5-ft-long fluorescent-lamp units or other types with mogul lamp sockets and the 3,000-watt type-AH or the 400-watt type-H mercury lamps with fixtures mounted at least 8 ft above the floor.

This design will, generally, result in a greater saving than the other schemes in designs where the above units can be used. The mercury lamps have such a high intrinsic brightness that mounting heights under 25 ft are objectionable even for the 400-watt type-H mercury lamp. Also, the four-tube 85-watt fluorescent unit can be used only where mounting heights of 18 to 20 ft are possible. For lower mountings, uniform light intensity cannot be secured except at unusually high intensities.

Another limitation of this system is that extension cords for hand lamps, hand tools, and portable and semiportable equipment are not suitable and permitted by Code requirements to be operated above 150 volts to ground. For this equipment, it will be necessary to install 460/120- or 460/120-240-volt single-phase or 460/208-120-volt three-phase transformers similar to the scheme shown as method *c*.

Distribution of the lighting load is important in planning the distribution system. Regarding light and power supply in industrial plants, the following general conclusions may be stated:

1. Where the lighting load is heavy—comparable to the motor load—a separate distribution system may be worth while for its dependability.

EXAMPLE: An airplane assembly plant where there are a large number of employees, a great amount of handwork, and a large number of small power tools.

2. Where the lighting load is not heavy, the combined light and power systems are less expensive than systems using separate substations for light and power. If it is assumed that, under present-day costs, the total cost of method *a*, including substations, secondary feeders, panel boards, and branch wiring, averages $70 per kva, method *b* will average about $58, method *c* about $47, and method *d* about $36.

3. High-voltage lighting circuits (460/265 volts) are generally most economical where all or a large portion of the lighting is by means of mercury lamps or 85-watt fluorescent lamps.

4. The 208/120-volt system is most economical for incandescent and 40-watt fluorescent lamps. Almost all the incandescent lamps are rated at 120 volts since higher voltage incandescent lamps are fragile and generally not satisfactory. This system will be especially advantageous for combination power and lighting loads where power load consists of small three-phase motors (25 hp and less).

Service Distribution Methods

There are two general methods of running primary and some of the secondary feeders in industrial plants—overhead and underground.

If run overhead, the cables may be (1) bare or weatherproof installed on pole lines or towers with service feeder spans bracketed to the buildings; (2) self-supporting preassembled insulated cables, aerial type; and (3) catenary suspended conduit, weatherproof wireways, or busways carried between buildings.

If run underground, the feeders may be (1) armored or synthetic-covered cable placed in trench and trench refilled, (2) underground raceways with manholes at suitable locations, and (3) exposed cables in tunnels or enclosed in raceways.

The advantages of the overhead type of distribution are

1. Cheapest initial installation
2. Cost of repairs and changes lower for the same number of repairs or changes
3. Repairs and changes easily made

The disadvantages of the overhead type of distribution are

1. Crippling of service due to severe weather conditions; damages by sleet or windstorms and lightning may result in heavy maintenance charges.
2. Poles and wires may be an impediment in traffic.
3. Poor appearance
4. May present danger to life

The advantages of the underground type of distribution are

1. Not affected by severe weather conditions and lightning disturbances
2. No impediment to traffic after installation

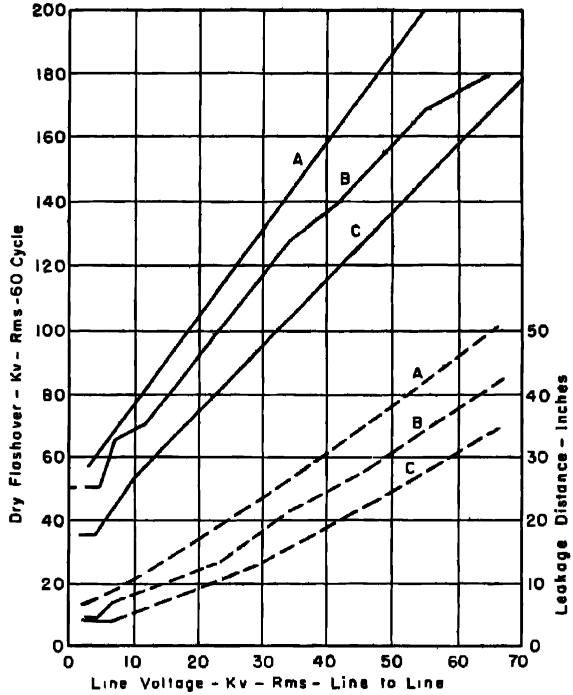

FIG. 13-13. Pin-type insulator. Dry 60-cycle flashover and leakage distance vs. service voltage. Three-phase systems.[3] Curve *A*—largest insulator commonly used on service voltage shown unless special conditions are involved. Curve *B*—approximate average-usage insulators. Curve *C*—minimum insulator levels.

3. No wires or cables visible to produce unsightly appearance
4. No danger to life except to maintenance personnel under certain conditions

The disadvantages of the underground type of distribution are

1. High first cost (three to five times the cost of overhead construction)
2. Inconvenient to make repairs or changes
3. High cost of making repairs or changes

Recommended Applications. Overhead distribution is recommended for long distances (above 1 mile) and also for short distances with the number of circuits is small (four or less) unless underground is economically justified according to the advantages listed above.

Underground distribution is recommended for short distances, congested plant areas, and where maximum reliability is economically justified.

Overhead construction is also recommended for plants which are operating on a temporary basis and which are more or less continually in a state of change. In

general, an investment for these types of plant would be expected to pay for itself in a relatively few years.

In the more stable industries like textile plants which expect to operate in a similar manner for a number of years, higher construction costs can usually be justified.

Aerial cable of the preassembled type is now being used for power distribution in many plants where the areas are congested and where neat appearance is required. This type of installation provides increased reliability and requires much less time to install than open-type wiring construction. The net cost of installation is fairly comparable with the unsightly open-wire lines. The safety and reliability of nonmetallic cables have been increased by improved methods of shielding, including proper methods of bonding and grounding the shields.

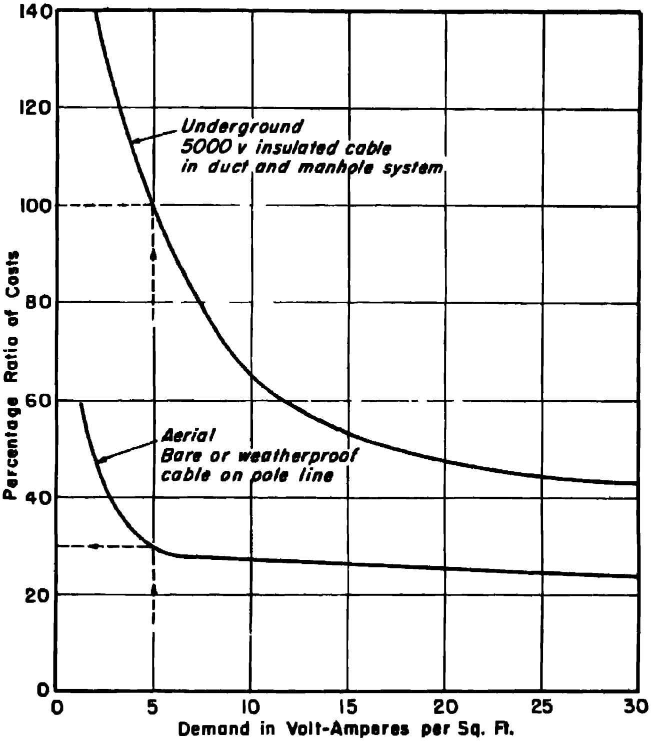

FIG. 13-16. Ratios of comparative installation cost of underground vs. aerial lines (based on a 5-va load per sq ft, equal to 100 per cent for underground lines).

With respect to aerial lines, there is a question regarding the almost universal practice of using weatherproof wire and cable for line conductors. Except in extremely corrosive atmospheric conditions there seems to be little justification in using weatherproof cable. This type of wire is not made to any voltage specification, and its insulating value is doubtful. Much weatherproof wire is soft drawn, so its strength is less than hard-drawn wire. The larger diameter of covered wire makes it more vulnerable to wind and sleet. It will burn down quicker than bare wire once an arc has started owing to the concentration of the arc at the point of covering failure. Finally, its cost installed is higher than bare hard-drawn wire.

Figure 13-13 shows a graph of the characteristics of line insulators, and Figs. 13-14 and 13-15 are graphs of the voltage drop for industrial-plant aerial lines.

The relative cost of plant distribution systems installed underground vs. those run aerially depends upon several factors—the principal ones being

1. The density of the load to be served
2. The type of electrical system used to give the quality of service required

Other factors are probable load increases; locations of loads, aesthetic reasons such as appearance of plant; safety to life and property; cost of operating and maintenance; space requirements for lines and equipment; and others.

Figure 13-16 shows comparative curves of the initial installation costs of underground vs. aerial methods of distribution for a plant consisting of several buildings spaced somewhat uniformly within the plant area having various load densities per unit area. The initial installation cost of an underground system is always higher at all load densities than for the aerial system, but the annual over-all carrying charges are another matter

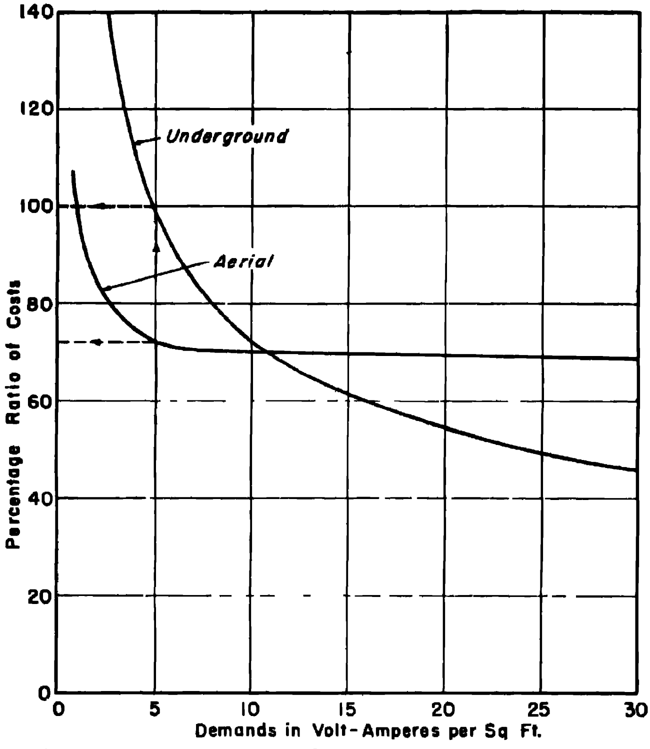

FIG. 13-17. Ratios of comparative annual owning cost of underground vs. aerial lines (based on same conditions as noted under Fig 13-16 plus a 30-year owning period including maintenance and replacement cost of aerial lines).

Wooden pole lines have a life expectancy of 15 to 25 years. Replacement costs would be nearly twice the cost of the original installation as extra labor is required to replace poles and wire spans a few at a time. Electrical losses are also less with underground construction. Figure 13-17 shows comparative curves of the annual owning cost of underground vs aerial methods taking into account depreciation, taxes, sinking fund, maintenance charges, and electrical losses. This curve indicates that underground distribution is justified where the demand is sufficiently high and the loads supplied are relatively stable for a long period of time.

Characteristics of Different Cables for Primary-feeder Installations

Of necessity cables used for underground distribution in industrial plants fall into two general categories—(1) metal-covered, meaning lead-covered, and (2) nonmetallic. Considering first lead-covered cables, the dielectric most frequently used is impregnated paper, chiefly because it is suitable for practically all voltages and because it is reasonable in price. Some varnished cambric has been used, and considerable rubber likewise has been used under the lead, the latter particularly for secondaries.

The object in placing a lead sheath over the dielectric is to prevent moisture, acids, and alkalies from reaching the dielectric and causing failure as those particular dielectrics were never intended to be proof against moisture, acids, or alkalies. Following this line of reasoning a lead-covered cable may be said to be only as good as its sheath and that, should the efficacy of the sheath be destroyed either because of mechanical damage, imperfections in manufacture, or chemical reactions, the efficacy of the cable itself is destroyed.

Nonmetallic cables are confined pretty well to rubber compounds and synthetics. Because of the nature of rubber, it is necessary to make a subdivision and differentiate between primaries and secondaries.

For primaries it is necessary to take into consideration and provide for corona. Some industrial-plant primaries operate at 11.5 and 13 2 kv. In such cases it is necessary to provide an electrostatic shield properly grounded. At 5 kv, through the use of some types of synthetic jacket, shielding is not necessary. In all cases utmost care must be exercised in the correct choice of dielectric. Oxygen is one of the greatest deteriorators to a rubber compound, and a perfect bonding between the dielectric and the synthetic, thus eliminating the oxygen, makes the combination of a good dielectric and the synthetics ideal from the standpoint of longevity. It is essential to eliminate corona and hence ozone in manholes because, even if the primaries have been designed to withstand it, there have been cases known where the ozone generated by the primaries attacked and caused failure of the secondaries in the same manholes.

Primaries with synthetics are much to be preferred to the fibrous covered or braided types. As for the secondaries, voltage being nominal, the characteristics which should be sought are a 75°C-temperature compound, ability to resist normal acid and alkali solutions and residual grease or oil in ducts, together with high mechanical strength, in the order of 3,600 psi.

With every engineering problem the economic problem exists. What is logical for one industrial plant is not necessarily feasible for another. For example, trained lead-cable splicers may reside and be available in one locality, while in others those specialists might have to be imported.

Before weighing any relative merits of one type versus another, consideration should be given to the following characteristics:

1. A lead sheath is ideal for excluding moisture or oils from the dielectric.
2. A 60 per cent jacket is good for moisture, not good in the presence of oil, yet is noninductive and unaffected by electrolysis.
3. At 11.5 or 13.2 kv a compound must have high dielectric strength and ability to resist corona.
4. For 600 volts sufficient electrical strength and a high degree of mechanical strength and ability to age well are desirable

The whole question being, therefore, one of compromise, all the known operating conditions must be set up on one side of the ledger, and on the other side the exact prescription must be written which will fit those particular conditions.

An inventory of the advantages and disadvantages, the opportunities and limitations, of the various types reveals the following:

Leaded Cables. *Advantages.* (1) Under normal conditions, a lead sheath offers the finest and most permanent protection to a cable. Aside from alkalies and organic acids, it is very resistant to corrosion. (2) High-temperature operation is permissible. (3) The lead sheath provides a good grounding means.

Disadvantages. (1) The lead sheath should not be used where electrolysis is present either chemically or in the form of stray currents. (2) It is highly susceptible to failure under vibratory conditions. (3) It requires potheading at all voltages and wiped sleeve joints. (4) Inductive and sheath losses are prevalent in some cases. (5) The lead sheath should not be used on high pole risers because of hydrostatic head and migration of oil.

Nonmetallic Cables. *Advantages.* (1) An advantage of nonmetallic cables is their lower first cost. They are easier to handle and install, being lighter in weight, and are constructed with utmost simplicity. (2) They are not so susceptible to mechanical damage as lead and (3) do not require wiped joints or potheading at 5 kv or under, thereby reducing installed costs. (4) Where pH content of residual water is high, this cable will be unaffected.

Disadvantages. (1) Rubber should not be used in the presence of oils or be subjected to direct rays unless protected by a suitable synthetic covering. (2) Operating temperature of the copper is limited to 75°C for insulations to 8 kv and to 70°C above, although this in turn is compensated by better thermal characteristics and no sheath losses. (3) The chief disadvantage of nonmetallic cables generally is the fact that there is no minimum standard of quality or design, with the result that in the search for economy there have been cases of improper designs being used.

It is impossible to give a specific recommendation general enough in character to cover all cases. In conclusion, one observation that should be emphasized is that no plant engineer in his search for reduced costs should jeopardize the permanency and reliability of a system by any compromise with inherent quality of materials used. Special conditions in any given installation may, of course, introduce factors that could effect a change in the selection, such as corrosion conditions, skill of splicers, load requirements, etc.

The most difficult handicap to overcome in the layout of aerial and underground lines and the reduction of hazards involved is the space factor.

In industrial plants it appears desirable to provide utility alleys for outside service lines and sectionalize these alleys for electric lines, communication circuits, yard lighting, underground fire mains, domestic and process sewer lines, overhead steam and process pipe lines, etc. Through this method it is possible to prevent conflicts and compromises between the various trades that are making use of the utility alleys. These alleys are usually located along the plant roads.

The same idea can be advantageously used in the process buildings in the form of utility shafts or areas reserved for service facilities.

The National Bureau of Standards Handbook H32 contains basic safety rules dealing with the installation and maintenance of electric supply and communication lines. Any designer or construction engineer dealing with the design and construction of both aerial and underground lines should be thoroughly familiar with these rules.

Interior Wiring Systems

A carefully planned lighting and power installation requires a well-planned wiring system. The types of loads served by the distribution system are usually very diversified, and it is not uncommon to see the full range of switch or breaker sizes installed on the same board.

Naturally the voltage should be the highest at which the major part of the power equipment can operate. This is usually the nominal 460-volt, three-phase system.

In selecting the interior feeder wiring system in industrial plants, many factors must be considered. Among these factors are the floor area, height and type of building, the type of occupancy, probable future changes in load requirements, the distribution of load, whether generally uniformly distributed or whether there are large concentrations of load, whether hazards are present such as moisture, corrosive or explosive fumes, vapors and dusts, and many others. The actual construction may be by means of one or a combination of the following methods. The important thing to note is that practically all the methods have two things in common—steel and copper. Steel comprises the raceways, wiring enclosures, outlet boxes, junction boxes, cabinets, and various fittings. Copper constitutes the conductors, switch devices, overload protective devices, and various equipments for current utilization.

1. Open work on insulators
2. Interlocked armor cables installed exposed on racks, walls, or ceiling
3. Enclosed wiring in conduit or tubing which may be exposed or concealed in the building structure
4. Metal wireways
5. Underfloor raceways (steel and fiber)
6. Busways or guarded busbar racks
7. Concentric tubular or polarized tubular conductors as recently developed for heavy welding loads

Branch circuits may be installed by one or a combination of the following methods.

1. Open work on insulators
2. Rigid or flexible raceways
3. Armored metallic or nonmetallic cables
4. Wireways and busways
5. Plug-in bus systems
6. Trolley bus systems
7. Underfloor raceways (steel and fiber)
8. Cellular-steel floors (type of Q flooring)

The open-type cable or bus wiring is acceptable under certain conditions, but other types of wiring methods are so practical for protection against mechanical injury and moisture, acid and alkali fumes and vapors, and safety considerations, that very little, if any, open-type construction should be used in industrial plants, except where the conductors can be placed out of the way, such as along girders and tunnels. Consideration must be given to voltage regulation as the greater conductor spacing required for open-type construction results in increased impedance.

The National Electrical Code, now in its 1947 edition and in its fifty-third year of use, has become the recognized minimum standard on all matters relating to electrical installations and electrical-wiring methods and equipment It was for the purpose of preventing loss of life or injury to person and loss by fire starting from electrical systems that the present Code was developed. All the above-listed methods of wiring are covered in sections of the Code. The designer should keep in mind that the installation must be made as safe and foolproof as practicable.

Table 13-6. Comparison of Interior Wiring Systems

System	Installed cost	Protection against mechanical injury	Protection against moisture	Fire risk	Appearance	Installation during building construction	Ease of installing in finished building	Ease of changing or adding loads
Open work on insulators	1	4	—	4	3	No	1	2
Armored metallic	2	2	—	3	2	No	1	3
Flexible conduit	3	2	3	3	2	No	1	3
Metallic tubing	4	2	2	2	1	Yes	3	4
Rigid conduit	5	1	1	1	1	Yes	4	5
Busways	6	3	—	2	1	No	2	2
Plug-in bus system	7	3	—	2	1	No	2	1

"1" represents the best or in case of costs the least expensive, "2," next best, etc

— indicates the system should not be used

Underfloor duct and cellular-steel floors are not included in this comparison as they are usually used in industrial plants to serve special conditions

Many of the wiring systems noted above cannot be used in certain types of occupancy. For example, rigid metal conduit with threaded explosion-proof joints, approved flexible couplings, and explosion-proof boxes and fittings are required for all Class I, Division 1 hazardous locations; either rigid metal conduit or electrical metallic tubing are approved for both Classes I and II, Division 2 hazardous locations. In

Class II, Division 1 locations, the wiring shall be in rigid metal conduit with threaded boxes and fittings. In wet and damp locations, the wiring raceway systems, including all boxes and fittings, shall be made watertight. Conduits, electrical metallic tubing, flexible metal conduit including all boxes and fittings used therewith should be of corrosion-resistant material suitable for the conditions. In addition, the conduit and equipment should be mounted so there is at least ½ in. air space between the conduit and equipment and the wall or other supporting surface.

Table 13-7. Comparison of Conduit Work

	Percentage
Conduits concealed on concrete forms or installed in masonry walls	100
Conduits run exposed on racks, comprising groups of four or more not over 10 ft above floor*	110
Conduits run exposed on walls or ceilings not over 10 ft above floor*	120
Conduits fitted to machines, benches, etc.	140

* For 11- to 15-ft ceiling run add 10 per cent; for 16- to 20-ft ceiling run add 30 per cent; above 20 ft add 3 per cent additional for each foot.

The rigid metal conduit is used to a great extent in both industrial plants and office buildings as it provides maximum protection for the conductors and a dependable protective grounding path for the apparatus. The conduit can be installed either exposed or concealed and is universally used under all atmospheric conditions. However, Everdur or aluminum conduits are used for certain acid or alkali corrosive conditions.

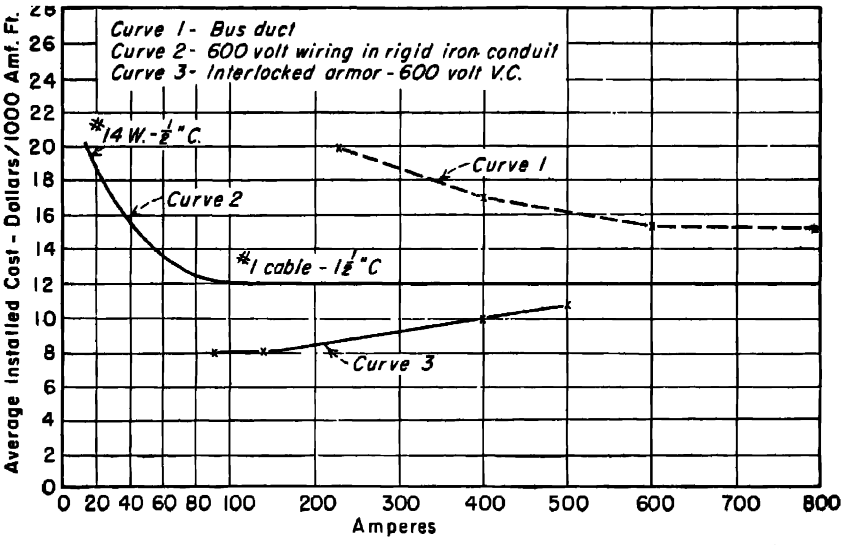

FIG. 13-18. Comparative costs of various types of feeder systems; 600 volts and lower, three-phase, three-wire.

A trolley bus system is a special form of busway constructed so it can receive both stationary and trolley-type devices. Portable tools or other loads are connected with brushes or contact rollers which make contact with the bus bars. Trolley busways are also being used for lighting distribution where it is desirable to provide readily facilities for rearrangement of the lighting fixtures.

The busway provides a safe, flexible, easy-to-erect installation with nearly 100 per cent salvage value. It is possible to provide a current range up to 4,000 amp. The maximum voltage rating is 600 volts, but at that this represents a lot of horsepower, kilowatts, and lumens. This type of system is particularly advantageous for serving groups of small- and medium-size motor-driven machines such as drills, lathes, shapers, etc. It also provides flexibility for future power applications and is particularly adaptable to high-current loads of 400 amp and larger. The installed unit cost per ampere-feet is about 50 per cent higher than for equivalent cable and conduit installations.

Table 13-8. Duct-line Reactance Drops

* The spacing between wires is assumed to be the average between the minimum possible spacing, three wires in contact, and the maximum, which is an equilateral configuration with each wire in contact with the interior surface of the conduit. Based on appropriate sizes of conduit as specified in National Electrical Code.

† The single-phase reactance is figured for the average conductor spacing.

‡ SE is the skin effect included in resistance figure. Resistance at 20°C. Three-phase impedance figures for 1.0 power factor include only the resistance component of drop, the reactance component being so small it is negligible. Since the column headed 1.0 power factor is resistance drop only, a comparison with values for other power factors shows the error occurring if the reactive component is ignored, *i.e.*, at 0.7 power factor, for example, the drop is 23 per cent less for No. 10 wire and 125 per cent more for 750,000-cir mils cable. The divergence from figures based on resistance drop only is entirely too great for even approximate results.

Example: What is the drop in 400 ft of No. 4 wire in conduit feeding a 40-hp motor taking 48 amp at 440 volts full load, three phase, 90 per cent power factor?

$$E = IZ$$

where E = volts drop, I = amperes per phase, and Z = impedance per 1,000 ft

$$E = 48 \times 0.424 \times (400/1{,}000) = 8.13 \text{ volts drop}$$

For single-phase or two-phase load, multiply impedance by (1/0.866) = 1.155.

Example: What is the drop in 200 ft of No. 8 wire in conduit supplying a 29-amp load at 220 volts, single phase, 70 per cent power factor?

$$E = 29 \times 0.85 \times (1/0.866) \times (200/1{,}000) = 5.7 \text{ volts drop}$$

Wireways may be advantageously used where it is desirable to provide a flexible and accessible means to install quickly additional circuits and to move machines from one location to another. With its allowance of 20 per cent of area or 30 conductors maximum it has a great many possibilities. The ground continuity of this system of wiring is rather doubtful but is easily remedied by installing a bare grounding conductor looped to grounding bushings on each conduit or bolted to each section of the wireway. Wireways may not only be used advantageously to distribute power loads to groups of small motors but also to facilitate the distribution of lighting branch circuits and to eliminate the large groups of conduits necessary to route them to their various centers.

Varnished-cambric-insulated, interlocked armor cable may be advantageously used in industrial plants where there are dry installation conditions. It is a low-cost general-purpose power wiring cable rated at either 600 or 5,000 volts. It does not require the use of conduit as the positively interlocked armor provides proper mechanical protection for the cable. It can be installed in racks or straps on the ceiling or along the walls. As compared with the usual rigid conduit system, this cable has approximately the same material costs, but there is a great saving in labor costs (see Fig. 13-18).

The tasks that electricity is being called on to perform in all types of occupancies are expanding rapidly. No longer is it used solely as a source of light and power. Provisions must also frequently be made for telephone and telegraph system, signaling and other communication systems, such as fire alarm, sprinkler alarm, watchman circuits, burglar alarm, etc. In interiors where there are few or no permanently located dividing partitions, underfloor raceways may be advantageously used. The number and location of raceways comprising the system depend upon service requirements. Underfloor raceway systems often fall short of their designed function owing to insufficient home-run conduits or connections between the feeder cabinets and the underfloor system for the requirements of wiring for signal and power circuits.

Power distribution in large areas to groups of small machines is greatly simplified when cellular-steel floors are used. The cells which are on 6-in centers provide a series of continuous raceways the full width of the building and are ideally adapted for multipurpose electrical distribution circuits. The steel cells of the floor are crossed over by headers carrying wires for telephone, power, and other types of electrical service.

Equipment and Wiring for Hazardous Locations. Chemical processes are now employed to some extent in almost every industry. Many chemicals create fumes that when mixed with air are highly explosive and/or dust-laden atmospheres that are dangerously flammable. Explosion hazards are classified in the National Electrical Code into three groups (Art. 500, 1947 edition) as follows:

Class I hazards embrace air-fume contamination separated in two divisions, *viz*, (1) locations where flammable gases or vapors may exist under normal operating conditions, frequent repair or maintenance operations, and where breakdown or faulty operation of process equipment might also cause simultaneous failure of electrical equipment; (2) locations where flammable gases, vapors, or volatile liquids are handled in a "closed system" (confined within suitable enclosures), or where hazardous concentrations are normally prevented by positive mechanical ventilation, or areas adjacent to the locations noted in (1) above where the gases or vapors might occasionally be communicated.

Class II hazards cover combustible dust-laden atmospheres. Again this class is separated in two divisions similar to those noted above for Class I.

Class III hazards include easily ignitible fibers or flyings. Division 1 covers manufacturing-process areas where ignitible fibers or materials produce combustible flying. Division 2 covers storage areas for such fibers and materials.

Considerable skill and judgment are required to determine the class of hazard and the extent of the hazardous area in the plant. Many marginal cases will be found due to the nature and relative concentration of the vapors, gases, dust, or other highly combustible matter. Installation conditions for hazardous areas are considerably more expensive than for standard work. In general, higher costs arise when installing conduit, conduit fittings, motors, controllers, lighting panels and equipment, and wiring. Motors weigh more; fittings are heavier and clumsier; and, in Class I wiring, varying quantities of sealing fittings must be installed and filled with compound.

Refer to Art. 500, 1947 edition of the National Electrical Code, for rules and regulations applying to the installation of electrical wiring and equipment in classified locations. Figure 13-19 is a diagram illustrating the requirements for Class I installations.

No motors or control equipment are available at the present time for hazardous atmospheres which contain acetylene, hydrogen, carbon disulfide, or similar gases.

Class I - Division I

FIG. 13-19. Diagram illustrating requirements of Class I, Division 1 installations.

For these gases and other applications where special precautions are necessary (as in the manufacture of explosives) one of the following methods may be used:

1. *Remote Location.* Remote location means location outside hazardous area with extended shafts to transmit power to the driven machine. Lighting units outside area with light directed into area through skylights and windows.

2. *Isolation of Equipment in Special Rooms.* Isolation of equipment in special rooms is very closely related to remote location, but the equipment is set up in a special room within the hazardous area. The room is tightly constructed and equipped with positive ventilation.

3. *Use of Inert-gas-filled Equipment.* The design of the electrical equipment must provide an enclosure tight enough to confine inert gas so that only a small supply of "make-up" gas will be required. A pressure of 1 to 2 lb is usually sufficient to exclude the hazardous gas from the equipment enclosures.

Successful operation in hazardous areas depends on careful selection, application, installation, and maintenance of the electrical equipment with adequate consideration given to ventilation and the "closed system" of process operation.

Notes on the Requirements of Class 1 Installations (See Fig. 13-19)

Construction features	Division 1	Division 2
A. Transformer and capacitor vault requirements		
1. Containing a liquid that will burn		
a. Located within building	Yes—NEC 5012	Yes—NEC 5012
b. Located outdoors	Yes*	No
2. Containing a liquid that will not burn		
a. Located within building	Yes, or be of explosion-proof type	Yes, fire-resistant construction 4521 to −4. Suitable separation satisfactory for Class B insulation
b. Located outdoors	Yes*	No
B. Meters, instruments, and relays	Explosion-proof enclosure	With make or break contact, explosion-proof enclosure, or if general-purpose enclosures to have oil-immersed or hermetically sealed contacts
C. Wiring methods		
1. Conduit type	Threaded rigid	Rigid or EMT Threaded or nonthreaded
2. Boxes and fittings	Explosion-proof approved	Vapor-proof
3. Flexible connections	Explosion-proof approved	Flexible metallic
4. Sealing of conduit required	Yes, in approved manner within 18 in. of enclosures	Only where explosion-proof equipment is required
D. Type enclosures		
1. For switches, breakers, motor starters, push buttons, relays, etc.	Explosion-proof approved	Explosion-proof, general-purpose with oil-immersed or hermetically sealed contacts
2. For motors	Explosion-proof approved	Totally enclosed type when no sliding contacts are employed. Sliding contacts, switching devices, etc., shall be installed in explosion-proof enclosure
3. For lighting fixtures	Explosion-proof approved type with threaded rigid conduit stems	Vapor-proof
E. Appliances, fixed and portable	Explosion-proof approved	Explosion-proof approved
F. Special items	Receptacles and plugs of polarized type Flexible cords—hard-usage type with grounding conductor No exposed live parts Bonding jumpers with proper fittings or other approved means Flexible conduit shall be jumpered Service conductors shall be protected with lightning arresters No motors or control equipment are available at present time for hazardous atmospheres which contain acetylene, hydrogen, carbon disulfide, or similar gases	

* Not specifically specified in NEC.

Metering and Instrumentation. A minor but important item in the supply of power services to the various processes or departments is that of metering. The power requirement for each department, building, process, or section of the manufacturing plant, together with the total for each service from its point of origin, should be metered. The sum of the individual loads should be balanced daily against the total generated output or purchased power and any discrepancy corrected immediately. Any losses noted may be found more easily, increases in consumption by any division noted and explained, and controversies over service charges backed up with documentary evidence of actual consumption. Thus meters of the recording type are a worth-while investment because of their aid in detecting losses from the distribution system and in allocating equitably service costs for accounting purposes. The meter usually used for this purpose on feeder circuits is the kilowatthour meter, and if used in conjunction with an ammeter for each circuit and a voltmeter for a group of circuits, the power factor of the load may be determined. The feeder circuit and also the generator capacity are dependent on the ampere requirements and not upon the kilowatt load.

Successful plant operation depends as much upon the ability to control the process as it does on knowing how to design and construct the plant. Figure 13-20 shows the interrelation of processes in chemical plants, practically all of which lend themselves to a varying degree of process control The most important process variables are (1) time, (2) speed, (3) temperature, (4) pressure, (5) fluid flow, (6) level, (7) humidity, (8) gas analysis, and (9) substance composition.

Fig. 13-20. Interrelation of processes in chemical plants.

There are, in general, three main operating principles of measurements, *viz.*, electrical and electronic, mechanical, or chemical. Instruments operating under these three principles have their own particular advantages or disadvantages. In general, except in the field of ion-concentration measurement, which is dominately chemical, and in the field of pressure, which is dominately mechanical, the instruments that are operated on the electrical or electronic principle are used more than any other type.

Electrical and electronic instruments, as a whole, are usually more accurate and more easily adapted to remote operation than other types. It is necessary only to lengthen the lead wires connecting the detector and the indicating or control mechanism In a process that is equipped with adequate measurement and control instrumentation, the man power required to follow and supervise the operation is kept to a minimum and used at maximum efficiency.

Determination of Fault Currents and Interrupting Capacity of Protective Equipment*

In an electrical circuit it is necessary to employ some form of protective interrupting device since there is always the possibility of an electrical fault. The protective devices must have not only adequate current-carrying capacity and proper voltage rating but also (1) ample interrupting capacity so as to prevent damaging effects of continued short circuit on apparatus and wiring and (2) the ability to withstand without injury the high momentary current liable to exist before interruption.

---

* Superior numbers in this section refer to the entries listed under References on p. 959.

It has been common belief that short circuits of 10,000, 15,000, or 20,000 amp are the maximum that can occur in low-voltage circuits. However, greater faults can and do occur. The value of fault currents in any electric circuit at any given voltage depends upon the impedance of the circuit. The magnitude of the short circuit is equal to the quotient of the voltage divided by the impedance.

The exact computation of the maximum possible short-circuit current in a given circuit is very complicated, involving intricate mathematical analyses and complete system-layout studies. For industrial-plant systems, we are fortunate that there is a relatively simple manner of arriving at approximate values that are close enough to actual values for all practical purposes.

This method involves simply the calculation of the maximum symmetrical short-circuit current which is then multiplied by established factors to obtain the total short circuit to be interrupted and the momentary current which the device must withstand.

In a-c circuits, all generators, synchronous motors, and induction motors are sources of short-circuit current. The resistance of these machines and transformers is usually negligible compared to the reactance, and, consequently, the reactance and the impedance are considered to be the same. Short-circuit currents are dependent upon the subtransient of the machines. The initial heavy surge diminishes rapidly, in a matter of cycles, and in induction machines dies out. In synchronous machines the subtransient current is followed by a current dependent upon the transient reactance. The final sustained short-circuit current is dependent upon the synchronous reactance of the machines.

Since the maximum interrupting duty of low-voltage air circuit breakers is assumed to occur ½ cycle (60-cycle basis) after the fault occurs, it is, therefore, necessary only to consider the effects of the subtransient current values.

In addition to the initial subtransient current, there is also present a d-c component which tends to displace the a-c component, increasing this initial value. This is illustrated by Fig. 13-21 which shows a typical curve of a short-circuit current in one phase of a low-voltage three-phase system.

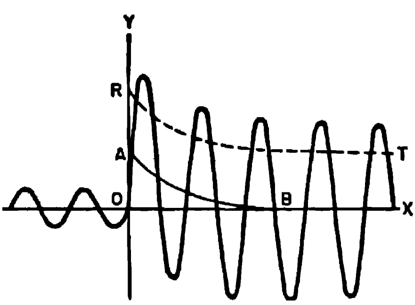

Fig. 13-21. Typical curve of a short-circuit current.

The wave to the left of OY represents the current previous to the fault, and the wave to the right represents the short-circuit current. The curve AB represents the d-c component, which has the effect of displacing the total wave by the amount shown by AB. After a few cycles, the d-c component dies down and leaves only the a-c component, which is symmetrical with respect to the X axis. During the existence of the d-c displacement, the total rms value is represented by the curve RT.

The rate of decay of the d-c component is a function of the ratio of the total of the machine subtransient reactance plus the external reactance, to the total circuit resistance X/R. The higher the value of the resistance, relative to the reactance, the faster the d-c component decays The initial value of the d-c component is dependent upon the point of the voltage wave at which the short circuit is established. It is maximum when this occurs at the zero point on the voltage wave, and its theoretical maximum is equal to 1.732 times the symmetrical current. A wave with this maximum d-c component, however, requires half a cycle to reach its crest value, and during this time, sufficient decay will take place so that a lower factor can safely be used. The currents in the other two phases are less than this maximum.

Air circuit breakers are applied on the basis of the average current in a three-phase system. In low-voltage systems, the X/R ratios are invariably low. On the basis of a thorough study, a multiplying factor of 1.25 has been adopted as representing average conditions at an instant ½ cycle after the short circuit occurs. This means that the total average current at this time, under maximum conditions, will be 1.25 times the initial three-phase symmetrical current, and it is this value we use for the interrupting and momentary ratings.

This represents the worst condition possible with the exception of a phase-to-neutral short circuit at the terminals of a delta-wye grounded-neutral transformer. However, this condition is so rare and unusual that its consideration can safely be omitted.

The reactance or impedance of a generator or transformer is generally expressed in per cent values based upon the rated kva rather than in ohms. Five per cent reactance in a circuit means that, when rated current is flowing, the voltage drop due to the reactance is 5 per cent of the rated voltage of the circuit.

Any ohmic value of resistance, reactance, or impedance in a circuit may be expressed in per cent as follows:

$$\text{Per cent on base kva} = (100 \times \text{base kva} \times \text{ohms} \times 1{,}000)/\text{volts}^2 \tag{1}$$

Any per cent value expressed in terms of one base can be expressed in terms of another base as follows:

$$\frac{\text{Per cent base 2}}{\text{Per cent base 1}} = \frac{\text{kva base 2}}{\text{kva base 1}} \tag{2}$$

In order to avoid the use of the value 100 when using per cent, values are sometimes expressed in per-unit values. The relationship is as follows:

$$\text{Per cent values} = 100 \times \text{per-unit value}$$

Systems with Primary Sources of Power. In low-voltage systems the impedances of the machines, conductors, and other equipment may not be negligible; and if necessary to consider them, the following formula can be used:

$$I = \frac{\text{kva} \times 1{,}000}{\sqrt{3} \times \text{voltage}} \tag{3}$$

where I = the normal current corresponding to the kva base used

$$I_i = (100 \times 1.25 \times I)/Z_T \tag{4}$$

where I_i = interrupting capacity or the symmetrical short-circuit current times the 1.25 factor for the d-c component at ½ cycle, and Z_T = the total impedance of the circuit in per cent

$$Z_T = \sqrt{(r_m + r_t)^2 + (X_m + X_t)^2} \tag{5}$$

where r_m = the resistance of the rotating machines
r_t = the sum of the resistance of the conductors and other equipment in the circuit to the point of short circuit
X_m = the subtransient reactances of the rotating machines
X_t = the sum of the reactances of the conductors and other equipment in the circuit to the point of short circuit

All the above are in per cent values on the same kva base.

In the general equation $Z = \sqrt{r^2 + x^2}$, the resistance combines with the reactance in quadrature. Unless r has values equal to one-third or more of the value of x, the resistance does not have an appreciable effect upon the value of Z. If resistance may be neglected, Eq. (4) reduces to

$$I_{sc} = \frac{100 \times 1.25 \times I}{X_m + X_e} \tag{6}$$

Now if the external reactance X_e is of a negligible value, Eq. (6) can be further reduced to

$$I_{sc} = (100 \times 1.25 \times I)/X_m \tag{7}$$

It is obvious that Eq. (7) will give a higher value of short-circuit current than either Eq. (4) or Eq. (6), but it is sufficiently close for all practical purposes.

Three-phase Transformers—Unlimited Primary Supply. The foregoing applied to systems where primary sources of power were present. A common application of low-voltage air circuit breakers occurs in systems that are served by power transformers. In such applications, the characteristics of the system back of the transformer are usually not known, and it is frequently the practice to consider the transformer as the source, in which case the primary voltage is then maintained constant even during a short circuit in the secondary. This is based on unlimited power available at the primary terminals and results in the maximum possible short-circuit current in the transformer secondary circuit. In this case Eq. (8) can be used:

$$I_{sc} = (100 \times 1.25 \times I)/Z_t \tag{8}$$

where Z_t = impedance of the transformer in per cent.

Three-phase Transformers—Limited Primary Supply. If the total circuit impedance of the system back through the transformer is known, the value of I_{sc} is calculated from Eq. (4), but if these data are not available, it may be assumed that the interrupting rating which is required for the power circuit breaker in the primary of the transformer is indicative of the short-circuit capacity available, and this provides an approximate means for determining the magnitude of the secondary short-circuit current. When a kva base limit is thus chosen, the impedance of this base is 100 per cent.

For calculating the short-circuit current of the transformer in such a case, the primary kva per cent impedance is converted to the transformer kva base [Eq. (2)]. The following formula can then be used:

$$I_{sc} = \frac{100 \times 1.25 \times I}{Z_p + Z_t} \tag{9}$$

where Z_p = impedance of the primary kva based on transformer kva in per cent.

A more conservative estimate will result when the maximum momentary instead of the interrupting rating of the primary circuit breaker is considered. This is due to the fact that modern low-voltage air circuit breakers are faster opening than older air circuit breakers. The kva rating at opening would therefore be higher than that indicated by the kva interrupting rating of the primary breaker.

Contribution by Motors to Short-circuit Current. Motors make up a considerable part of the load of a transformer. Because they generate at the time of a fault and thus feed energy into the fault, their contribution to the short-circuit current is important.

Induction motors as well as synchronous motors must be included. At the instant of short circuit there is magnetic flux in the core of the secondary of the induction motor. This flux cannot vanish immediately but is maintained by the current flowing in the secondary and will decrease in keeping with the resistance and inductance characteristics of the motor circuit. This decreases very rapidly but must be included because of the high opening speed of the circuit breaker. (This generator action of the induction motor is different from that of the induction generator.)

Synchronous motors continue to receive their normal excitation at the time of the short circuit, run as synchronous generators by inertia, and act like synchronous generators in delivering energy into the fault. The current from synchronous motors decreases less rapidly than that from induction motors.

For estimating purposes the approximate symmetrical values of short-circuit current contributed by the motors at an instant ½ cycle after the short circuit happens are 3.6 times full-load current for induction motors and 4.8 times full-load current for synchronous motors.

In practice it can be assumed that, for a 208/120-volt installation, the motor load will be 50 per cent of the transformer kilovolt-ampere, and for 240-, 480-, and 600-volt installations the motor load is 100 per cent of the transformer kva. It can be further assumed that the motor load will be 75 per cent induction and 25 per cent synchronous.

Using all these assumptions, the total motor short-circuit current to be added to the short-circuit current of the transformer for a given kva transformer will be as follows:

For a 208/120-volt transformer

$$I_{scm} = 2 \times I_t$$

For a 240-, 480-, or 600-volt transformer

$$I_{scm} = 4 \times I_t$$

where I_t = full-load current of the transformer, and I_{scm} = symmetrical short-circuit current contributed by motors.

These values will then be multiplied by 1.25 to include the d-c component.

For a 208/120-volt transformer

$$I_{icm} = 2.5 \times I_t \tag{10}$$

For a 240-, 480-, or 600-volt transformer

$$I_{icm} = 5.0 \times I_t \tag{11}$$

where I_{icm} = interrupting capacity for motors or symmetrical short-circuit current contributed by motors times the 1.25 factor for the d-c component at ½ cycle.

EXAMPLES: 1. Three-phase transformer—unlimited primary supply, 1,000 kva, 480-volt secondary, 5½ per cent impedance.

Required: The interrupting capacity (fault located at X).

$$I = \frac{1{,}000 \times 1{,}000}{\sqrt{3} \times 480} \tag{3}$$

= 1,200 amp, normal full-load current of transformer

$$I_{ic} = (100 \times 1.25 \times 1{,}200)/5.5 \tag{8}$$

= 27,300 amp, interrupting capacity (required from transformer)

$$I_{icm} = 5 \times 1{,}200 \tag{11}$$

= 6,000 amp, interrupting capacity required from 100 per cent motor load

The combined interrupting capacity is therefore

$$27{,}300 + 6{,}000 = 33{,}300 \text{ amp}$$

A 50,000-ampere-interrupting-capacity circuit breaker would be selected.

2. Three-phase transformer—limited primary supply, 25,000 kva, interrupting capacity of primary circuit breaker, 1,000 kva, 240-volt secondary, 5½ per cent impedance.

Required: The interrupting capacity (fault located at X).

$$I = \frac{1{,}000 \times 1{,}000}{\sqrt{3} \times 240} \tag{3}$$

= 2,400 amp, normal full-load current of transformer

$$\text{Per cent} = 100 \times 1{,}000/25{,}000 \tag{2}$$

= 4.0 per cent primary impedance based on transformer kva

$$I_{ic} = \frac{100 \times 1.25 \times 2{,}400}{4.0 + 5.5} \tag{9}$$

= 31,600 amp, interrupting capacity required from transformer

$$I_{icm} = 5 \times 2{,}400 \tag{11}$$

= 12,000 amp, interrupting capacity required from 100 per cent motor load

The combined interrupting capacity is therefore

$$31{,}600 + 12{,}000 = 43{,}600 \text{ amp} \tag{12}$$

A 50,000-ampere-interrupting-capacity breaker would be adequate, but the full-load current of the transformer is 2,400 amp. A breaker of this continuous current rating will have a 75,000-amp interrupting rating and would therefore be selected.

In the two preceding examples we have assumed the presence of a motor load and the fault so located that the motors contribute to the short-circuit current. This gives us the worst possible condition, considering the switchgear and connected load as a whole. Applications are sometimes encountered where a short circuit can occur at such a place that the motor load will not contribute energy to it. The circuit breaker should then be chosen on the basis of the energy supplied by the transformer alone, omitting the energy flowing from the motors. In example 1 the short-circuit current without motors would then be 27,300 amp, and in example 2 the short-circuit current would be 31,600 amp.

Direct-current Systems. The fault current to be considered in d-c systems is the maximum current obtainable and not some lower value during the initial rise. When a short circuit occurs, the current rises rapidly, and the final value depends on the resistance in the circuit. The rate of current rise depends on the resistance and the inductance in the circuit

For calculating the short-circuit current, it is necessary to have information concerning the maximum short-circuit current obtainable at the terminals of the machines.

For estimating purposes, the data in Table 13-9 may be used to obtain the approximate maximum short-circuit currents at the terminals of d-c machines

Table 13-9

Type of machine	*Times K = normal current*
Shunt-wound	10
Compound wound	10
Compound-wound with compensating field	15
Rotary converters	15

Using Table 13-9 the short-circuit current for a fault at the machine terminals will be

$$I_{sc} = K \times I \tag{13}$$

where I = full-load current of the machine

If the air circuit breakers are remote from the machine, the resistance of the external circuit should be included in the calculations, and the short-circuit current is

$$I_{sc} = E/(R_m + R_e) \tag{14}$$

where E = the voltage of the circuit

R_m = the equivalent machine resistance or

$= E/(K \times I)$

R_e = the external resistance to the point of the fault

Substituting the value of R_m in Eq. (14), the value for short circuit can be computed from the following formula

$$I_{sc} = \frac{K \times E \times I}{E + (K \times R_e \times I)} \qquad (15$$

In a d-c generator the final current depends upon the winding and upon the demagnetizing effect of the current flowing The rate of current rise depends upon the voltage and capacity of the machine, being lower in higher voltage machines The rate of rise of a standard 1,000-kw machine may be approximately 1,500,000 to 1,800,000 amp per sec

Storage batteries have low values of internal resistance and inductance and give rise to high currents and high rates of rise of current.

Mercury-arc rectifiers also have inherently low resistance and inductance values which produce very high values of rate of rise and final short-circuit currents. The actual value cannot be approximated without knowing the characteristics of the particular rectifier involved. A number of installations have shown a rate of rise of from 6½ to 8 million amp per sec.

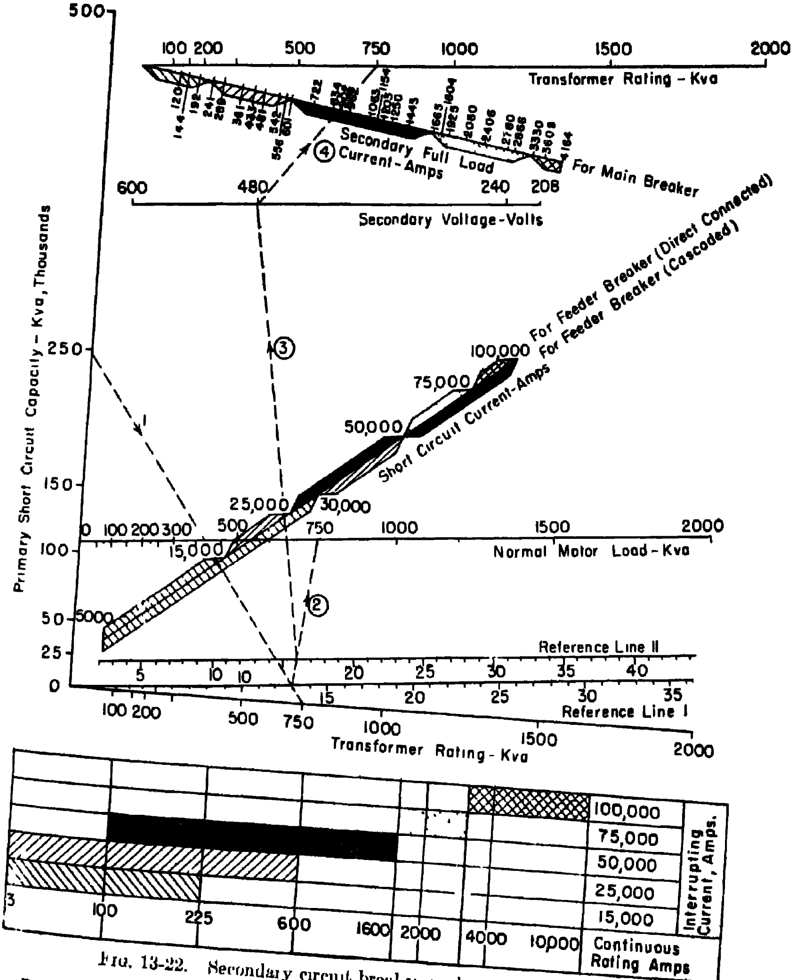

FIG. 13-22. Secondary circuit breaker application nomogram.[6]

By using Fig. 13-22, the interrupting capacity and short-circuit currents in a-c circuits can readily be determined by three settings of a straightedge as follows:

1. Place a straightedge on the value of primary short-circuit capacity and on the transformer rating on the abscissa, finding a point on reference line I. If an infinite system is assumed, place the straightedge on the value of the transformer kva and perpendicular to the axis of transformer kva.

2. Using this point and the kva of normally connected motor load, find a point on reference line II. Motor load may vary from 0 kva to the full transformer rating

(100 per cent motor load is usually assumed for 240-, 480-, and 600-volt systems and 50 per cent motor load for 208Y/120-volt systems).

3. Using this point on reference line II and the value of the secondary voltage, the rms value of the secondary short-circuit current will be found as well as the breaker with the correct interrupting capacity for direct-connected or cascaded feeder breakers.

4. Check continuous current ratings given on chart of breaker sizes to be certain that breakers with necessary interrupting capacity as determined by nomogram have adequate continuous current-carrying capacity. The load on each feeder circuit determined this current.

Cascading of Breakers. Low-voltage air circuit breakers are normally applied on the basis of adequate interrupting capacity and current-carrying ability, both for normal loads and fault currents for short-time intervals. Under these conditions, standard interrupting-duty cycles apply. Selective tripping based on time discrimination can easily be arranged to isolate faults and not interrupt power to normal circuits

It is not always economical, however, to apply circuit breakers in the conventional method. If the load consists of an assembly line or other related processes which make it necessary to shut down all other circuits, breakers may be applied on the cascade principle. Under these conditions, certain breakers may be subjected to currents above their published interrupting ratings, and a restricted interrupting-duty cycle results.

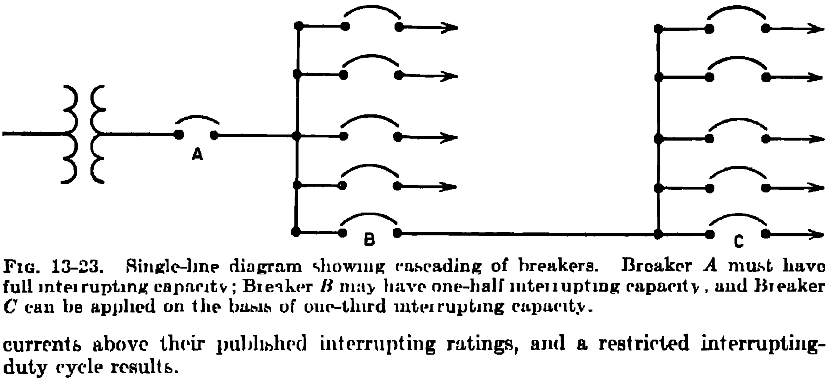

Fig. 13-23. Single-line diagram showing cascading of breakers. Breaker *A* must have full interrupting capacity; Breaker *B* may have one-half interrupting capacity, and Breaker *C* can be applied on the basis of one-third interrupting capacity.

It is evident that, if two or more breakers operate in series to clear a fault, the stresses on them are less than if they opened individually. This condition is recognized, and breakers farthest from the source of power in cascade arrangements may be applied with interrupting ratings less than the fault currents to which they will be subjected Each breaker in these cascade circuits must be free to trip instantaneously when the breaker next lower in the cascade is subjected to currents above its published interrupting rating. This means that selective isolation of faults is not possible on currents exceeding the interrupting ability of the smallest breakers.

Breakers that interrupt currents above their rating, as evidenced by the opening of the breaker next higher in the cascade, must not be closed even once without inspection. They may be damaged so that normal-load current cannot be safely carried, or their interrupting ability may be impaired.

Cascading is limited to three steps of interrupting capacity, as shown in Fig. 13-23. The breaker nearest the source of power must have adequate interrupting capacity for the circuits in which they are applied. The breakers next lower in the cascade may have one-half the interrupting rating required by the maximum fault currents, and those farthest from the source may have one-third this rating.

For any application requiring full selective isolation of faults for maximum continuity of service, breakers with full interrupting capacity must be chosen for all positions. The reduced selectivity, restricted interrupting-duty cycle, and some additional maintenance which can be expected with cascaded breakers are often compensated for, however, by large savings in the initial cost of the switchgear. Under these conditions, cascaded arrangements may be preferred.

Fuses. In some cases, fuses and switches are suitable for circuits, the fuse supplying the protection and the switch the control. The operation of any fuse (both high and low voltage) under short-circuit conditions is so fast that it clears during the subtransient conditions and before the d-c component has had time to die out. The capacity must therefore be based on the total current including the transient offset. In the general case this is 1.6 times the symmetrical short-circuit current, but for fuses rated 15 kv and below, not applied directly to a generator bus of high capacity, the resistance introduced by lines and intervening apparatus is so great that the total current will seldom exceed 1.2 times the calculated symmetrical short-circuit current. Application on this basis is considered safe. However, the contribution from motors must be added to the current from the power source.

Demand Factors

Demand factor is the ratio of the maximum use of power to the total load connected expressed as a percentage. In the average plant, the demand factor usually falls between 60 and 80 per cent.

In the design of an electrical system of an industrial plant, one of the most difficult problems is to determine how much electrical power will be required for different load groupings and the various types of operations for the entire plant. The loads occurring coincidently between various drives, departments, or areas of the plant always lead to loads that are less than the total connected load. Also the total over-all plant load will be less than the peak loads of the various departments or areas combined. The load grouping and determination of the diversity and demand factor is the key to a more practical and economical design.

To determine the demand factor with a fair degree of accuracy, it is necessary to investigate many items. Some of the most important are listed below:

1 What equipment will be required to operate simultaneously and under what loads.

2 What pieces of apparatus will require starting together and which machines will be running at that time and under what loads.

3 The load densities commonly encountered, including both power and load, usually range from about 8 to 25 va per sq ft.

4. Lighting loads for up-to-date lighting-intensity levels range from 4 to 6 va per sq ft for incandescent lamps and 2 to 4 va per sq ft for fluorescent and mercury lamps (see Fig 13-43).

In converting all ratings, such as horsepower, into kva, it is usually sufficiently accurate to allow for loads in accordance with Table 13-10.

Table 13-10

Kva	*Type of load*
1.0	Each induction motor hp
0.9	Each 100 per cent synchronous motor hp
1.0	Each 80 per cent synchronous motor hp
1.0	1,000 watts incandescent lighting
1.25	1,000 watts fluorescent lamps equipped with standard starters
1.0	Each 1 kw of resistance heaters, ovens, etc.

Table 13-11 gives values of typical demand factors for over-all loads of various types of industrial plants and represents the average maximum for a group of medium- and large-size plants in the same industry. In general, the more nearly an industry may be classified as a "continuous process," the higher will be both the demand factor and the annual load factor.

Lightning Protection

All electrical equipment connected directly or through cables to overhead lines is exposed to lightning. Switchgear and other apparatus may also have additional exposure through power transformers that are connected to aerial lines. Both manufacturers and users have for years been interested in finding means of preventing, so far as economically feasible, damage from lightning.

An especially important contribution toward this objective has been a better understanding of the nature of lightning. Through the use of high-speed cameras, oscillographs, curve voltage records, and surge-crest ammeters, information on the formation of lightning strokes and the magnitude, front, and length of current and voltage waves resulting from lightning discharges has been recorded.

As a result of the better understanding of the actual character of lightning, it is possible to evaluate the effectiveness of protective equipment and to set up protection rules so that troubles from lightning will be minimized.

Table 13-11. Typical Demand Factors for Various Types of Industrial Plants

Industry (manufacturing processes)	*Demand factor ratio of max demand / connected load*
Agricultural implements	0.65
Aluminum manufacturing	0.40
Asbestos products	0.50
Bakery (gas fired ovens)	0.45
Cement	0.65
Chemicals	0.50
Copper and brass products	0.50
Dyeing and finishing textiles	0.75
Electrical machinery, apparatus, and supplies	0.65
Engines, turbines, and water wheels	0.50
Explosives manufacturing	0.55
Flour mill and elevator	0.65
Foundry and machine shop products	0.65
Gas manufacturing	0.60
Iron and steel (blast furnaces, rolling mills)	0.45
Knitting mills	0.85
Laundry	0.80
Lumber and timber products	0.65
Machine shops, miscellaneous stampings, machine parts, welded assemblies, etc.	0.25
Marble and other stone products	0.65
Paints and varnishes	0.70
Paper and pulp	0.75
Petroleum and oil refining	0.60
Pigment manufacture	0.40
Printing and publishing	0.80
Pipe manufacture (wrought iron)	0.35
Refrigerators (mechanical)	0.70
Rubber goods, tires, and tubes	0.75
Rayon manufacture, chemical house excepted	0.80
chemical house included	0.65
Slaughtering and packing	0.70
Shell manufacture	0.40
Soap manufacture	0.60
Sugar refining	0.65
Tin cans and other tinware manufacture	0.70
Wood distillation and charcoal manufacturing	0.60

Surge voltages on lines are limited in maximum values to the flashover of the insulation to ground. The current in these surges is also limited by the surge impedance of the line. For example, the surge impedance may be on the order of 500 ohms. For a 1,000-kv surge, the current would be approximately 2,000 amp. While this current is not excessive, the voltage would be dangerous to equipment if protective equipment were not used.

Direct strokes of lightning may involve currents as high as 200,000 amp, rising at the rate of thousands of amperes per microsecond. However, only a small percentage of direct strokes will be higher than 20,000 amp.

Figure 13-24*a* shows curves of a surge on a 13.2-kv circuit and the voltage reduction by the discharge of the lightning arrester. It is seen that, with good lightning arrester grounds, the voltage during a surge will be below the basic insulation level of the circuit. However, if the arrester ground has a high resistance, safe voltage may be exceeded. The conditions that must be met by lightning arresters in application are as follows:

1. Voltage across the arrester during a discharge must not exceed a certain predetermined value which is safe for the insulation to be protected.

2. The circuit should not be disturbed by the arrester's action. Little or no system current should follow the impulse.

3. The arrester should be so constructed that it has a factor of safety against failure such that the arrester will not fail under usual service conditions.

4. The characteristics of the arrester should remain practically constant during the life of the arrester, and under normal service its life should be at least as long as the apparatus which it protects.

The most vulnerable part of the electrical system is the overhead aerial lines. In cases where the circuits are highly exposed to lightning of appreciable frequency and intensity, system outages can be very largely prevented through the use of (1) overhead ground wires, (2) counterpoises, (3) expulsion tube protectors, (4) ground-fault neutralizer coils, and (5) high-speed relay. Of these, only the overhead ground-wire scheme is generally used on overhead lines in industrial-plant systems of 13.2 kv and lower.

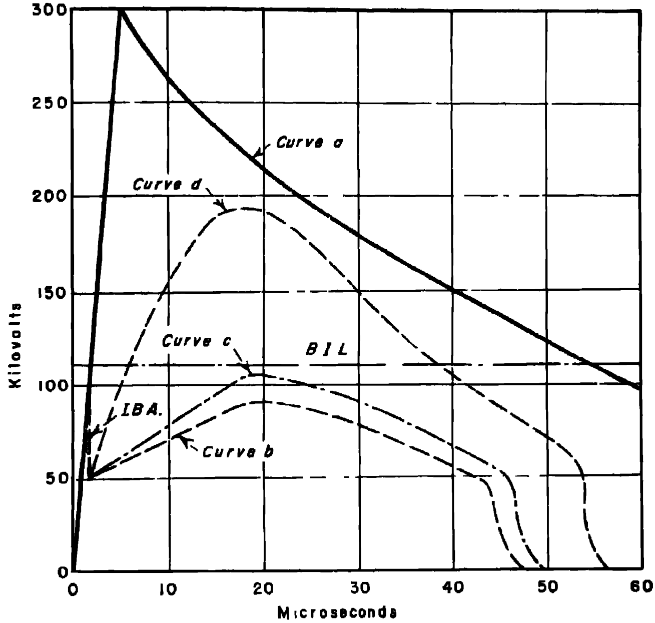

Fig. 13-24a Voltage reduction by arrester discharge on 13.2-kv circuit Curve a—surge 5-40 wave on circuit. Curve b voltage across arrester only. Curve c voltage from arrester to ground (0 ohm ground resistance and 40-ft ground lead). B.I.L basic-impulse insulation level, 15-kv class. I.B.A impulse breakdown of arrester.

The effectiveness of the overhead ground-wire protection in preventing arc-over of insulator strings depends on its resistance to ground. For adequate protection of motors when they are supplied with power from overhead lines, the lines should be shielded against direct strokes.

Virtual immunity from oil-insulated-type transformer failures is being obtained through the use of the most modern valve-type arresters, particularly where interconnection is made between the ground terminal of the primary arrester and the ground connection of the secondary, thereby shunting the transformer insulation to be protected. Air-cooled transformers have a BIL (basic impulse level) considerably lower than oil-insulated transformers (see Table 13-12). If the former are subject to surge voltages, they should be protected by special tube-type arresters located as close as possible to the transformer terminals with a second set of standard line-type arresters connected on the line about 500 ft ahead of the transformer.

When aerial lines of any voltage enter cables, the terminals should have adequate protection. This protection is usually secured by an arrester located at the junction of the cable and aerial line with the arrester ground connected to the cable sheath.

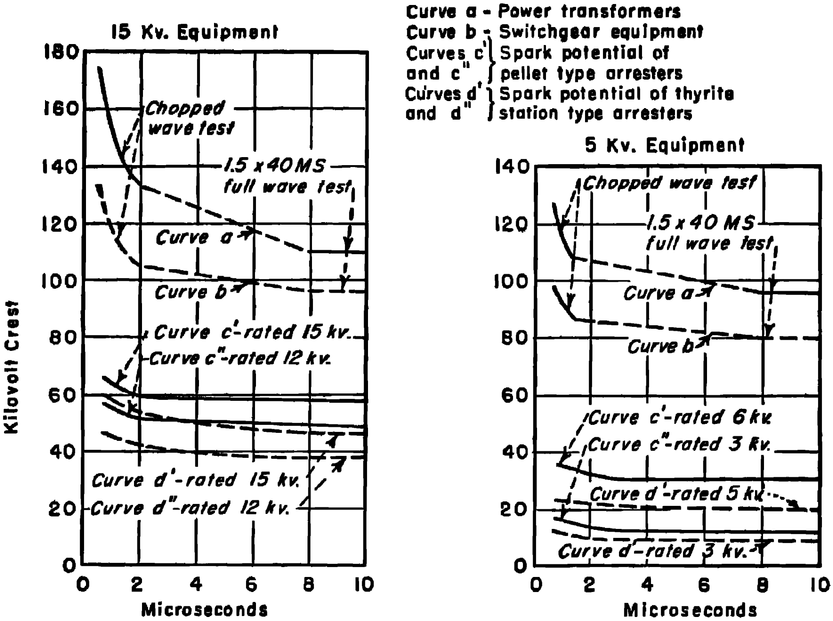

FIG. 13-24*b*. Impulse strength and protective characteristics for industrial-type equipment.[7]

The cable sheath should also be grounded at the other end as a ground at only one end will not be effective in keeping the sheath at the opposite end effectively grounded.

Table 13-12. Performance Characteristics of Thyrite Station-type Lightning Arresters*†

Arrester rating, kv (rms)	Station voltage class		Transformer insulation class, kv	Transformer impulse levels, 1.5 × 40 ms kv crest		Arrester impulse sparkover in kv crest		Arrester discharge voltage on 10 × 20 ms current wave	
	Ungrounded neutral	Grounded neutral		Oil or askarel	Dry type	Front of wave	1.5 × 40 ms wave	1,500 amp	3,000 amp

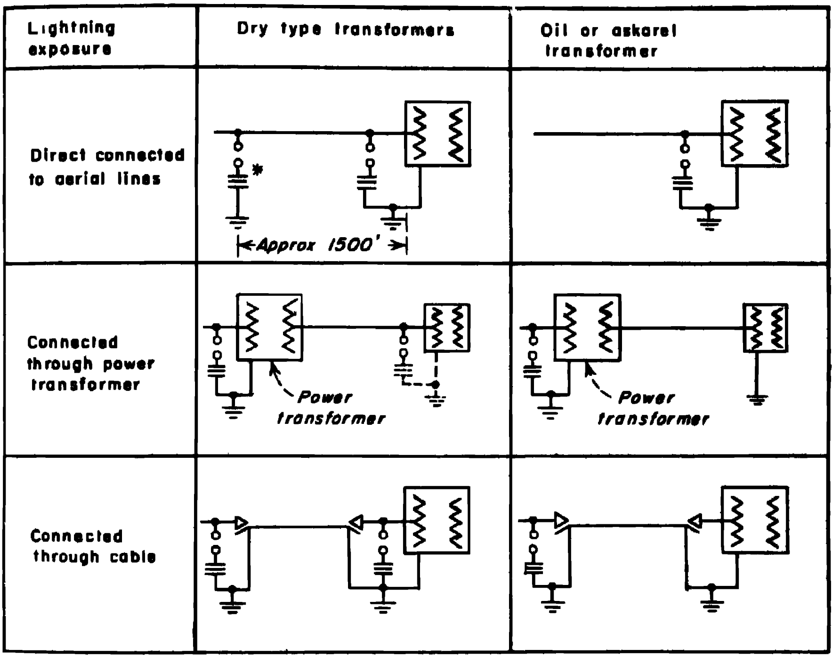
* HUNTER, E. M., and T. E RODHOUSE, Indoor Transformers, *Gen. Elec. Rev.*, November, 1947.
† These arresters are also used for protection of a-c rotating machines.
‡ Applies only to three-phase transformers.

Lightning protection on transformers alone will not ensure protection to plant equipment.

A most effective scheme for protecting a-c rotating machines has been in use for a number of years for use with generators, motors, or synchronous condensers which may be subjected to impulses either from directly exposed lines or transmitted through transformers. The usual lightning arrester is here supplemented with protective capacitors, connected from bus or machine terminals to ground, thereby reducing the steepness of the traveling-wave voltage entering the machine. The amplitude of the impulse wave is limited by the use of line arresters 1,000 to 1,500 ft out on the circuit, together with station-type arresters in parallel with the capacitors.



*May be distribution type - all other type arresters indicated should be station type

FIG. 13-25. Arrester-protection for different types of exposures

Buildings, tanks, etc., containing explosives and inflammable liquids and vapors may be adequately protected from being struck by lightning by properly placed mast or overhead shielding wires connected to low-resistance grounds.

In evaluating the effectiveness of lightning protection equipment it is necessary to plot the impulse strength and protective characteristics of the various types of apparatus under consideration. Representative volt-time curves for 5- and 15-kv switchgear equipment, power transformers, and applicable arresters are shown in Figs. 13-24b and 13-25.

Industrial-system Grounding

The term "grounding," as applied to electrical circuits and equipment, has many complex ramifications. Grounding the circuits in industrial plants acts a double safety check: (1) Faults in electrical circuits are giving a low-resistance path to ground to operate protective devices quickly; and (2) the plant personnel is protected against dangerous shock hazards because the voltage to ground of all parts of the wiring system is limited. In both these safety checks the grounding can be effective only if it is properly installed according to good engineering practice with a full understanding of its purpose.

The best insulated and most carefully installed electrical system does not always stay perfectly insulated. There is always the possibility of accidental grounds. There are two general types of ground: equipment grounds where the non-current-carrying metal parts (or frames) of electrical equipment and wiring enclosures are grounded; and system grounds, where the neutral or one conductor of the system is permanently connected to ground.

The metallic parts that must be grounded include conduits, sheaths or armor of cables, frames or cases of switches, motor starters, controllers, fuse boxes, junction boxes, switchgear, transformers, generators, motors, and similar items. The National Electrical Code (Art. 250, 1947) specifies the methods and requirements for grounding equipment. The Code, however, requires that the resistance of the ground shall not exceed 25 ohms. The current flowing in the grounding conductor can be calculated by Ohm's law.

If we have a lighting circuit with 120 volts between the live wire and ground, a ground resistance of 10 ohms, and a short circuit between the live and ground wires, the current flowing in the grounding circuit will be 12 amp, which can be continuously on a 15-amp fuse. Hence, the fuse protecting the grounded circuit will not "blow" unless and until other load is placed upon that circuit. If the grounding resistance is reduced to 5 ohms, the current will be 24 amp, and the protecting fuse or circuit breaker will open in a few seconds. It is obvious that, the lower the resistance to the flow of electricity through the grounding conductors, the greater will be the protection. It is recommended that the resistance of all the grounds installed be no greater than 5 ohms.

Electrical circuits are grounded in order to (1) limit the voltage upon a circuit upon breakdown of insulation and accidental contact with wires of circuit of higher voltage, (2) protect against transient overvoltage due to a switching or lightning surge, (3) prevent the establishment of a voltage upon equipment which is normally assumed to be at ground potential, and (4) possible improvement of lightning-arrester protection for overhead transmission circuits.

The largest single factor in grounding of the electrical system of industrial plants is that accidental faults are either immediately cleared or otherwise detected before they develop into a double line-to-ground fault, tripping out a considerable portion of the plant load. Ground detectors can of course be used with an ungrounded system but will not indicate the location of the fault. Accidental grounds in an ungrounded system which are not detected or immediately corrected constitute a hazard for the following reasons: (1) A ground on another conductor puts a fault on the system, which may occur on a circuit other than the first, shutting down both circuits or, in some cases, the entire plant system; (2) a line-charging current flows into the fault, and even though small, it may, in time, cause considerable damage, particularly if the fault is internal to apparatus, such as a generator or motor; and (3) arcing faults can produce surge voltages as high as five or six times normal line-

Table 13-13. Low-frequency Test Voltage*

(Voltage expressed in number of times system line-to-neutral voltage)

Nominal system voltage	Oil-insulated transformers	Dry-type transformers	Motors	Usual values for wiring
600 and below	28.8	11.5	6.1	2.5 6.0
2,400	10.8	7.2	4.1	4.0–5.0
4,160	7.9	5.0	3.7	3.0–4.0
4,800	9.4	6.9	3.5	3.0–4.0
6,900	6.5	4.8	3.6	2.0–2.5
13,800	4.3	3.9	3.4	2.0

* Witzke, R. L., Neutral Grounding Limits—Industrial System Faults, *Elec. World*, May 10, 1947.

to-ground voltage. Table 13-13 shows that this level of surge voltage may exceed the apparatus test voltage for all systems above 600 volts.

Some utility companies object to grounding systems proposed by industrial plants. Of course, if the industrial system is served directly connected at the utility company's operating voltage, the scheme of grounding requires proper coordination with that of the utility system.

The two systems are usually interconnected by means of a transformer bank with at least one winding of the bank normally connected in delta. This delta-connected winding will make grounding of each system independent of grounding of the other with the result that the grounding of the low-voltage system will have no effect on the high-voltage system or vice versa.

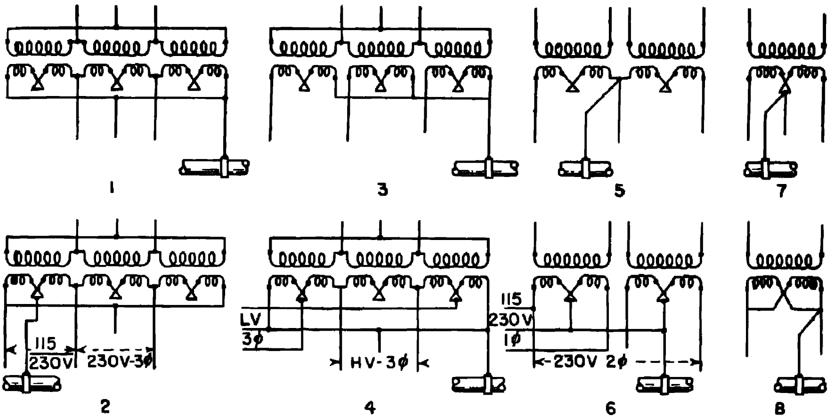


Fig. 13-26 Grounding connections for secondary distribution circuits. (1) Delta-connected power transformers—secondary for three-phase three-wire installations. (2) Delta-connected power transformers—secondary for three-phase 230-volt power and 115/230-volt single-phase lighting installations. (3) Wye-connected power transformers—secondary for three-phase three-wire or four-wire installations. (4) Delta-connected power transformers—secondary for three-phase three-wire half-voltage employing common-phase ground. (5) Two transformers—secondary for two-phase three-wire installations or three-phase transformers—secondary for three-phase three-wire open-delta installations. (6) Two-phase transformers—secondary for 230 volts, two-phase four-wire and 115/230-volt single-phase three-wire installations. (7) Single-phase transformer—secondary for 115/230-volt three-wire installations. (8) Single-phase transformer—secondary for single-phase two-wire installations.

Systems at 600 Volts and Below. The National Electrical Code (1947) specifies that secondary a-c systems supplying interior wiring and interior a-c wiring systems shall be grounded if they can be so grounded that the maximum voltage to ground does not exceed 150 volts. It also recommends that a-c systems with voltage to ground that does not exceed 300 volts be grounded and states that higher voltage circuits may be grounded. Figure 13-26 shows diagrams where such grounds are required.

The great majority of 460- and 575-volt three-phase three-wire power systems are operated with the neutral or one-phase conductor ungrounded. The reasons for not grounding these low-voltage power systems is that the apparatus at these voltages usually has considerably more margin in insulation than apparatus for higher voltages. The principal advantage of an ungrounded system is its ability in some cases to clear ground faults without an interruption to the service. Also, the line-to-ground voltage is 57.8 per cent of the phase-to-phase voltage, but with the possibility of accidental grounds, it is doubtful whether the ungrounded system is less hazardous than the grounded-phase system. The problem in these low-voltage systems is not the protection of equipment but the possible personnel hazard due to large ground fault currents.

Figure 13-27*a* shows what may happen when faults occur on ungrounded systems with high-resistance-equipment grounds.

Figure 13-27*b* shows that personnel hazards are removed from electrical systems by proper and adequate equipment and circuit grounds. The grounded-phase circuit shown in Fig. 13-26 possesses some distinct operating advantages:

1. The piece of apparatus in fault is immediately removed from the system without affecting any other part of the system.

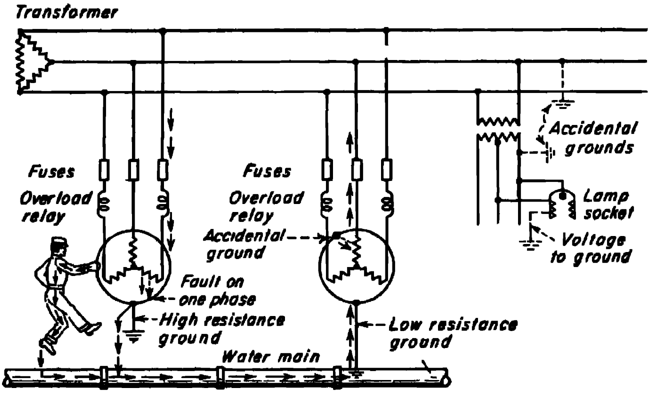

FIG. 13-27*a*. Ground characteristics of electrical systems - possible personnel hazards due to ground-fault current.

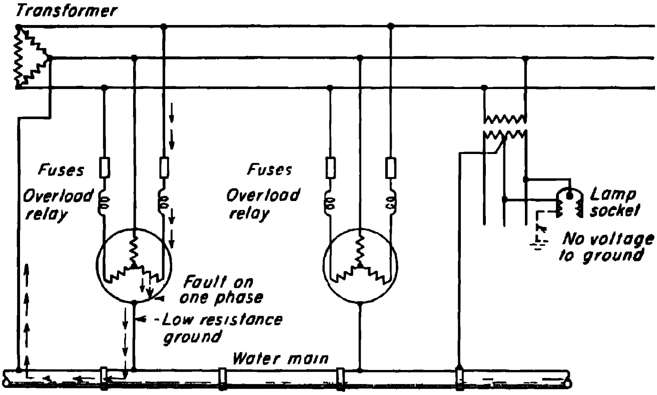

FIG. 13-27*b*. Ground characteristics of electrical systems - personnel hazard removed with proper equipment and circuit grounds.

2. The maximum voltage that can exist on the system is the nominal phase-to-phase voltage.

3. Many of the existing low-voltage industrial systems are equipped only with two overload relays on the feeders. In the grounded-phase system only two overload relays on trip coils are necessary for adequate protection.

In the 208/120- and the 460/265-volt three-phase four-wire systems, the neutrals are usually connected solidly to ground since the maximum possible voltage which can appear across any portion of the ground path is low (265 volts in the case of the 460-volt system), and the impedance of the ground path is nearly always sufficient to limit the current to a safe value.

Higher Voltage Systems (2,400 Volts and Above). In the higher voltage systems it is necessary to limit the ground fault current to the lowest value which is satisfactory for relay operation. The reasons for limiting the ground fault current are

1. To reduce the burning and melting effects of the fault current on equipment and wiring.
2. To reduce the momentary line-voltage disturbances to at least 2½ to 3 times the normal line-to-ground voltage. This value is below the test level for apparatus with the result that the number of equipment failures attributed to surge voltages will be decreased.

Depending upon the kva rating and voltage rating and the inherent impedance of the system, some transformers can have their neutral solidly grounded. The approximate maximum size of transformer banks that can be solidly grounded without exceeding 2,500 amp is shown in Fig. 13-28.

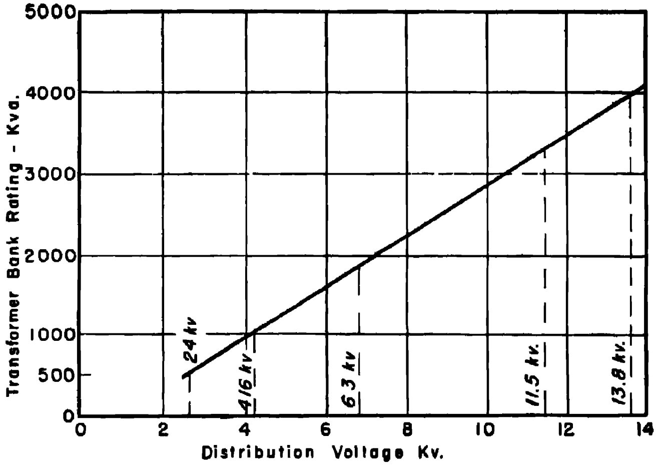

Fig. 13-28. Approximate maximum size of transformer banks that can be solidly grounded without exceeding 2,500-amp ground-fault current.

For larger size banks and practically all generators, it is necessary to limit the ground fault current. The methods used to limit the current are

1. Resistance grounding
2. Reactance grounding
3. Combination of both resistance and reactance
4. Ground fault neutralizer

The common connections for the neutral grounding methods are shown in Fig. 13-29.

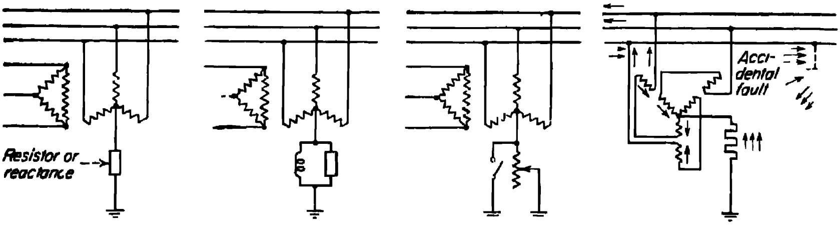
Resistor grounding is best suited for a large percentage of industrial systems as it provides a practical means of limiting ground fault currents to desired levels. Resistors are rated in volts equal to the line-to-neutral voltage and in amperes equal to the current which flows when this voltage is applied to the resistor. For example, the normal line-to-neutral voltage in a 13.8-kv system is 8,000 volts. If a 4-ohm resistor is used, the ground fault current will be approximately 2,000 amp. A range of 1,000- to 3,000-amp ground fault current is usually required for satisfactory relay operation.

Reactance grounding has application advantages in certain types of industrial systems where high values of ground fault current make the system suitable for a more effective lightning-arrester application. The solidly grounded neutral system is a form of reactance grounding. For most reactance-grounded systems, the ground fault current must exceed 25 per cent of the system three-phase fault current in order to avoid serious transient overvoltages.

Combination of resistance and reactance grounding is less expensive for outdoor applications than grounding resistors since the latter, if applied outdoors, should preferably be made of stainless steel. Outdoor grounding reactors are less expensive than stainless-steel grounding resistors of the same rating. A properly selected parallel combination of outdoor reactor and resistor will combine the advantages of each.

Ground fault neutralizer grounding is most commonly used in the higher voltage systems (13.8 kv and above) using overhead lines where there are frequent faults in the line such as insulator flashovers. The use of a neutralizer results in practically no ground current being available to maintain the arc, and hence, the fault is self-clearing.

Where no suitable wye-connected transformer bank or generator is available for providing a neutral connection, a grounding transformer is required. The type of transformer most commonly used is a three-phase zigzag unit with no secondary winding. It is intended solely for the purpose of establishing a neutral ground connection. Each wye of such a transformer has two separate windings which are interconnected between phases. In case one of the lines to which the transformer is connected becomes grounded, the ground fault current divides equally among all the windings. The ground current is limited by impedance of the two sets of coils which are on the same core. The resistor impedance should be at least twice the value of the transformer reactance. The impedance of the transformer to three-phase currents should be such that, when there is no fault on the system, only a small magnetizing current flows in the transformer windings.



Grounding system by resistor connection to neutral lead of Y-Δ transformer

Grounding system by combination resistor and reactance connection to neutral lead of Y-Δ transformer

Grounding system by means of ground fault neutralizer to neutral lead of Y-Δ transformer

Grounding system by means of a zig-zag neutral grounding transformer

FIG. 13-29. Common methods of grounding to limit ground-fault current.

A wye-delta connected transformer may also be used as a grounding transformer, but a zigzag type of transformer is usually less expensive than a comparable two-winding transformer.

It is recommended that some form of grounding be used for all industrial-plant systems. However, the expense involved in conditioning existing ungrounded 460-575-, or 2,400-volt systems for grounding may prove so excessive that grounding means cannot be warranted. As the plant system expands and loads increase, it becomes more difficult to arrange interruptions to the circuits in order to detect and clear ungrounded systems of faults.

Important Factors in Selecting Wires and Cables for Industrial Plants

Industry has many applications requiring specific types of wires and cables for efficient plant operation. Cables are required to stand up where exposed to attacks from oils, acids, or alkalies, extreme corrosive conditions, high ambient temperatures and other severe operating conditions. As the requirements of industry grow more complicated, a multiplicity of types of cables has been made available. New basic insulation materials were developed and adopted wherever it was believed they would do a better job.

Many of the types of cables are needed only for very special applications. Careful selection of a few types for each plant having a wide variety of applications can keep the number of different cables required small. It is the purpose of the following to analyze typical application problems which are encountered and outline suitable cables for the job.

Many factors jointly influence the proper selection of industrial wires and cables The primary ones are listed below:

1. Operating conditions
   a. Voltage and frequency
   b. Installation method—conduits, ducts, free air, air or earth ambient, conduit grouping, etc.
   c. Special conditions—corrosive problems (water and chemicals), high temperature, severe exposures, etc.
2. Insulation of conductors (see Table 13-14 and Table 13-15)

Table 13-14. Insulated Cable Specifications

- *A* Conductors
  - 1 Material copper aluminum
  - 2 Type of conductors solid, stranded, extra flexible
  - 3 Number and size of conductors
- *B* Insulation (see Table 13-15)
  - 1 Rubber, code grade, types R, RW, RU, RH
  - 2 Thermoplastic, code grades T, TW, TA
  - 3 Varnished cambric code grades V, ACV
  - 4 Asbestos and varnished cambric code grades AVA, AVB, AVL
  - 5 Asbestos code grades A, AA AI AIA
  - 6 Slow burning, code grades SB SWB
  - 7 Weatherproof, code grade WP
  - 8 Glyptal cloth, resistant to oils and alkalies
  - 9 Flamenol (code grade I) Severe applications for 600 volts when exposed to acids, alkalies, and oils (Special applications from plug-in-type bus to machines, control cables, installed aerially in conduit or ducts or buried directly in ground)
- *C* Finishes
  - 1 Metallic
    - *a* Lead or alloy-lead sheath (L)
    - *b* Armor—interlocked (I), flat-band (I), round-wire (W), basket weave
  - 2 Nonmetallic
    - *a* Braid flame and moisture resisting (weatherproof), seine twine (B), glyptal treated
    - *b* Rubber-hose jacket for extra weatherproofing (RHJ)
    - *c* Tellurium compound jacket for unusual rough usage such as encountered in portable welders, mining machines, electric shovels, etc
    - *d.* Neoprene compound for resisting attacks by oil, gasoline, acids, and alkalies
    - *e.* Flamenol—same as neoprene but it is not so flexible as neoprene (I I)
    - *f* Treated jute (sometimes asphalt finish)
    - *g* Semiconducting corona-resisting type for shielding of cables up to 15 000 volts
    - *h.* Treated—duct tape for use over lead to give extra protection against corrosion, electrolysis, and possible damage

3. Number and type of conductors. Single-conductor cables, three conductors in a conduit, are most frequently used for industrial-plant distributions as making of taps and splices is simplified.

4 Relative importance of circuits Reliability is generally required in the following order: main supply circuits, main feeders to local load centers, subfeeders, and branch circuits. Relative importance of circuits in each class is dependent on load; and frequently, premium-type wires and cables are selected for certain operating conditions and types of exposure.

5 Size of conductor to be selected so that the current will not heat it to a temperature in excess of the rating of the insulation Make necessary corrections for grouping (in air or in conduit) and for the ambient where the ambient is not standard (20°C earth or 30°C air). Where National Electrical Code regulations apply, check the conductor size against National Electrical Code (1947) Tables 1 and 2

6 Size of conductor to be checked to determine that it will carry the electrical energy to the point where it is to be used without excessive voltage drop. If voltage regulation is excessive, select the conductor size on the basis of voltage drop.

7 On certain feeders it may be desirable to consider and check that the cost of energy lost in the distribution circuits will not be excessive.

A conductor may satisfy one of the three latter items and yet not satisfy the

Table 13-15. Properties and Usage of Standard Conductors for Interior Wiring

Trade name	Type letter	Maximum operating temperature	Insulation	Conductor sizes	Voltage range	Outer covering	Application
Code	R	60°C (140°F)	Code-grade rubber	14–2 000 M cir mils	0–5 000	Moisture-resistant, flame-retardant, Fibrous covering	General use, dry locations
Moisture resistant	RW	60°C (140°F)	Moisture-resistant rubber	14–2,000 M cir mils	0–5,000	Moisture-resistant, flame-retardant, Fibrous covering	General use, wet locations
Heat resistant	RH	75°C (167°F)	Heat resistant grade rubber	14–2 000 M cir mils	0–5 000	Moisture-resistant, flame-retardant, Fibrous covering	General use, dry locations

Asbestos	AA	200°C (392°F)	Felted asbestos	14–4/0	0–600	Asbestos braid	
Asbestos	AI	125°C (257°F)	Impregnated felted asbestos	14–8	0–300	None	
Asbestos	AIA	125°C (257°F)	Impregnated felted asbestos	14–1 000 M cir mils	0–600	Asbestos braid	
Paper		85°C (185°F)	Paper		All voltage	Lead sheath	Service entrance and special use
Slow burning	SB	90°C (194°F)	Three braids impregnated fire resistant cotton thread	14–2 000 M cir mils	0–600	Outer covering finished smooth and hard	Dry locations only
Slow burning weatherproof	SWB	90°C (194°F)	Two layers impregnated cotton thread	14–2 000 M cir mils	0–600	Outer fire-retardant covering	Dry locations only
Weatherproof	WP	80°C (176°F)	At least three layers impregnated cotton braid or equivalent			None	May not be used
Ozone resistant		Manufacturer's recommendations	Ozone resistant rubber		0–28 000	Braid or lead	General use as type R, RW or RH

remaining two. A conductor may have ample cross-sectional area to carry a given current, but the length of the circuit to the load center may be such that the allowable voltage drop or the energy loss or energy dissipated in overcoming the line resistance will be excessive. Manufacturers' data and National Electrical Code give tables for current-carrying capacities of the various types of wires and cables.

With reference to voltage drop for low- and medium-voltage a-c circuits, it is necessary to take into account the resistance, reactance, and power factor of the circuit and use the following formula for calculation:

$$E = \sqrt{(E^1 \cos \phi + IR)^2 + (E^1 \sin \phi + IX)^2} - E^1$$

where E = voltage drop to neutral, volts per total length of each conductor

E^1 = receiver, end voltage to neutral, volts

I = load current, amp

R = a-c resistance, ohms per total length of each conductor (For d-c resistance of copper conductors and the a-c/d-c resistance ratio refer to tables Sec. 15-126 and 15-128 "Standard Handbook for Electrical Engineers" 1941 edition.)

X = reactance, ohms per total length of each conductor to neutral (See table, Sec. 15-126, "Standard Handbook for Electrical Engineers," 1941 edition.)

$\cos \phi$ = power factor of load

(For direct-reading voltage, drop calculating charts for three-phase power wiring in iron conduit; for voltages of 460, 2,300, and 4,160, see General Electric Company Wire and Cable Catalog, Sec. 1200.)

When consideration is given to initial cost, it will always be found cheaper to run a few large conductors rather than a number of smaller ones. In a-c wiring, no conductors larger than 750,000 cir mils should be used in order to avoid otherwise detrimental skin effect. For economic reasons, parallel conductors for circuits are preferred for circuits of 300 to 400 amp or more.

Table 13-14 shows an analysis of types of cables for general use in industrial plants. For most plants only a limited number of types are required to do the job. As noted, the same type of cable may be used satisfactorily for a wide variety of applications. For example, a cable with a neoprene outer covering or sheath resists flame, acids, alkalies, oils, heat, sunlight, and abrasives. It is good for long service life, for installation aerially, direct earth burial, or in ducts or conduits.

Comparison of Purchased and Locally Generated Power[4]

The estimated total annual electric power generated in the United States and imported in 1948 is 300 billion kwhr. On the average, industries consume about 65 per cent of the total power generated in the United States by utilities and industries combined (after deducting the power-plant and transmission and distribution losses). Of this amount, industrial power plants are used to generate about one-third, and the balance is purchased from utilities The majority of industrial customers, particularly those having small power requirements, purchase their power from public utilities. This is the logical result when the rates are favorable

Conditions may exist, however, which make it more economical for some industrial plants to generate a part or all of their power locally in spite of reasonable and justifiable rates for purchased power. Important factors in determining the desirability of industrial-plant generation are

1 Proximity to existing utility power lines
2. Magnitude of power requirements
3 Available by-product fuel or heat
4. An adequate supply of cheap fuel or water supply
5. Large demand for low-pressure steam for processing and heating

The factors listed above will be discussed in that order. They may exist singly or in combination.

1 The plant location may be so remote from satisfactory public-utility lines that the power rates may be so high and the service so unreliable as to warrant local generation

2 Conditions may exist which make it possible and economical for the plant to generate a part of its power locally in spite of reasonable and justifiable rates for purchased power The amount of power which it is economical to generate will depend upon the rates obtainable and other factors discussed below.

Table 13-16. Wires and Cables for Industrial-plant Layout

Maximum voltage class	Installation method	Installation conditions	Maximum allowable copper temp deg C	Recommended type of cable
600	Conduit	Dry	60	Code type R RU and T
	Conduit	Wet	60	Code type RW and TW
	Conduit	Dry	75	Code type RH
	Conduit or ducts or direct burial	Wet or dry	75	Type RH or RW with neoprene jacket or lead covered
	No conduit	Dry	60	Armored cable code type R multiconductor
	No conduit	Dry	85	Interlocked armor varnished cambric multiconductor type ACV
	Direct burial	Wet	75	Type RH with neoprene jacket or lead covered
	Conduit	Dry exposed to high temperatures	85 110	Types V and AVA
	In open air	Wet or dry exposed to sunlight	75	Type RH or RW with neoprene jacket (preassembled aerial cable)
	In conduit or open air	Oil and heat resistance		Glyptal cloth with water proof braid
	In conduit or open air	Oil acid alkali moisture resistance		Flamenol type I
2 000–5 000	Conduit or duct system	Wet or dry	75	Type 50 RH or 50 RW with neoprene jacket or lead covered
	Conduit or duct system	Wet or dry	85	Type 50 VL
	No conduit	Dry	85	Interlocked armor varnished cambric multiconductor type ACV
	Direct burial	Wet	75	Type 50 RH or 50 RW with neoprene jacket
	In open air	Wet or dry exposed to sunlight and corrosive fumes	75	Type 50 RH or 50 RW with neoprene jacket (preassembled aerial cable)
5 000–15 000	Conduit or duct system	Wet or dry	75	Ozone resistant rubber with shielding tape
	Conduit or duct system	Wet or dry not subject to electrolytic action	85	Varnished cambric lead covered
	In open air	Wet or dry exposed to sunlight and corrosive fumes	75	Ozone resistant rubber with shielding tape (preassembled aerial cabl

3 Many industrial plants, such as cement plants, smelters, paper mills, sawmills blast furnaces, coke ovens, and refineries have available by-product heat or fuel as result of the type of process carried on The forms of energy available vary in the different industries hot air in cement mills and smelters chemical by-products which may be burned in paper mills bark, sawdust and waste lumber in sawmills, and combustible gas from blast furnaces, coke ovens, and refineries

In plants using by-products fuel or heat, there is no fuel cost other than handling

4. A supply of easily utilized water power or of relatively cheap fuel, such as is present in the form of oil and gas in the oil fields, presents a problem very similar to the previous one. In some locations, especially in certain sections of Canada, there is an abundance of hydroelectric power available. With a more or less limited industrial use for electrical power, the surplus is often used in electric boilers to produce process steam.

5. Large demands for low-pressure steam for processing and heating constitute another factor. Steam is of essential value in some industries. Amount, pressure, and temperature of steam used vary widely even among the same processes carried on by different manufacturers. In general, so far as the low-temperature heating operations are concerned, steam is the most economical medium to employ. In plants that require process steam in large and fairly constant quantities, many opportunities exist for the development of inexpensive power services.

Through the use of high-pressure boilers and pressure-reducing prime movers, the process steam required may be obtained, either as bled steam or high-pressure exhaust steam, while at the same time considerable quantities of electric energy can be produced very cheaply—sometimes for as low as 2 mills per kilowatt. A most interesting problem develops in the process industry by permitting the extraction of steam for electric-power generation from the steam generated by high-pressure superheating boilers before the steam is turned over at process pressure to the chemical processes. In the past, there was a tendency to treat the problems of an industrial power plant the same as those of a public-utility plant. Both have much in common, but because the industrial power plant must be necessarily considerably smaller than a public-utility plant and, therefore, less efficient, it is amiss to assume that purchased power will be cheaper. This might be true if the supply of power did not have connected with it the supply of heat. The supply of steam and electric power to a process does not constitute two problems, but a combined single problem. The efficiencies of a public-utility power plant and an industrial power plant cannot be compared as a guide in determining which source will be most economical. The true criterion of a power plant's performance is the amount of heat put to useful work, or, in other words, the amount of preventable waste that can and should be avoided.

It is the primary business of public utilities to sell power and services. It behooves them to render the best possible service without interruptions at the lowest possible costs within economic reason. The problems of an industrial power plant of the kind here being discussed are peculiar. The "by-product" power is incidental to furnishing heat. "By-product" power from pressure differences is in no way related to power from waste fuel, from the waste heat of process combustion, or from waste exhaust steam condensed through turbines. It is limited to that power which an industry can produce by generating steam at pressures within present ranges of practice and then passing this steam through a turbine or engine and exhausting it at a pressure high enough to supply a definite process requirement for heat deliverable as steam The power plant of a process industry is more of a heating plant than a power plant; the problems are heat-engineering problems rather than power problems. It is necessary only to determine what degree of perfection is warranted to secure the best possible economy for one industrial plant, rather than for a group of industries as the central station must necessarily supply. The balancing of the quality of power service against its cost is of fundamental importance in the process industries. These are the greatest differences between an industrial power plant and a utility power plant, the single purpose of which is to produce power. A misunderstanding of the heat-power problem is a barrier to potential savings.

Wherein does the economy of "by-product" power generation lie? It is not difficult to prove that, in general, "by-product" is the cheapest power available to an industrial plant, provided operating conditions requiring electric power and steam heat are favorably balanced. In the typical steam plant there are three general steps:

1. Heat stored in fuel is delivered to a plant.
2. The fuel is burned, and the stored heat is liberated and transferred to water and steam in the boilers.
3. The accumulation of heat in the boilers is transferred into electric power by a

turbogenerator or an engine-generator set, or it is carried by the water and steam to the various processes.

If there were no waste of heat and the boilers, turbines, and generators were 100 per cent efficient, a quantity of fuel containing 3412 Btu could generate 1 kwhr. It is impossible, however, to transform all of a given amount of heat supplied to a working substance into work. Modern boiler units operate at efficiencies of 80 to 85 per cent, the latter figure not being unusual; turbines operate at 95 to 98 per cent efficiency; and generators, 90 to 96 per cent. With these efficiencies, it is possible to produce 1 kwhr of by-product power at a fuel-consumption rate equivalent to 4,300 to 5,000 Btu per kwhr or 0.3 to 0.4 lb of average coal. The heat that cannot be transformed into work, and that which must be rejected by the turbine can be used in the processes. In the central-station plant, the heat exhausted from the turbine is practically useless because of its low temperature and lack of pressure; such a condensing plant, even when operating at 1,400 lb steam pressure and employing both the generative and reheat cycles must have a fuel consumption equivalent to 11,000 to 14,000 Btu per kwhr, or 0.8 to 1.0 lb of average coal.

In the by-product power plant, the heat may be extracted from a noncondensing unit at any desired pressure and temperature (this, of course, depends upon the initial pressure and temperature) and put to practical uses in the process. Temperature difference is necessary for heat transfer, and pressure difference is necessary for steam velocity in the unloading stages of the turbine to the processes. For this reason, considerably less power will be produced in the by-product plant than in the central station for the same fuel consumption, but the proportion of heat usefully applied in by-product generation to central-station generation is about in the ratio of 3:1 By-product energy need be charged only for the heat actually used in passing through the turbine. This is not true for a central station because in a condensing steam turbine the heat of vaporization of the steam at the exhaust pressure is an unusable end product which must be carried away by the condenser circulating water.

In the matter of selecting turbines for a plant, no general statement can be made because the conditions of every problem are different. However, in general, the following is correct:

1. Where the electrical load is predominant, the turbine should be a condensing-extraction type.
2. Where the steam load is predominant, the turbine should be a noncondensing-extraction type.
3. Where the steam demand balances the electrical

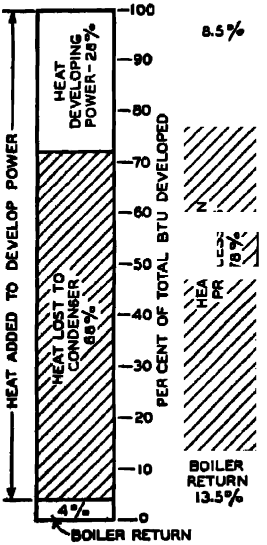

Fig. 13-30. Proportion of heat used in condenser-turbine (left) and "by-product" (right) power generation Throttle steam for both condensing-turbine and by-product generation is at 400 lb gauge pressure and 200°F superheat. Condenser turbine exhausts to a 29-in. vacuum. "By-product" generation exhausts at 80 lb back pressure and 60°F superheat. If the heat content of one pound of throttle steam is 1330 Btu, the mechanical efficiency 97 per cent, the electrical efficiency 96 per cent, and all items are the same for each turbine, then the following is a comparison of the two systems:

Condensing plant:

$$\text{Lb steam per kwhr at turbine throttle} = \frac{3{,}412}{0.28 \times 0.97 \times 0.96 \times 1{,}330} = 9.8$$

$$\text{Btu per kwhr at turbine throttle} = 9.8[1330(0.28 + 0.68)] = 12{,}800$$

"By-product" plant:

$$\text{Lb steam per kwhr at turbine throttle} = \frac{3{,}412}{0.085 \times 0.97 \times 0.96 \times 1{,}330} = 32.8$$

$$\text{Btu per kwhr at turbine throttle} = 32.8 \times 0.084 \times 1330 = 3060$$

demand, the turbine should be a straight noncondensing type. This type is seldom used because the balanced conditions are seldom obtained; however, the noncondensing turbine may be used in conjunction with a condensing turbine, and the steam may then be bled off the noncondensing turbine at process pressure. If the quantity of steam bled off is not all required for the process, it may be passed through the lower stages of the condensing turbine and used to produce power.

Figure 13-30 shows the magnitude of the heat quantities in the steam cycle of a condensing plant and of a by-product plant. As shown in the figure, a larger quantity of steam is required to develop 1 kwhr with by-product generation, but the heat energy (Btu) chargeable to power is considerably less than that required by condensing-turbine generation. The percentages given are for a specific problem but indicate relative proportions of uses of the generated steam.

Figure 13-31 gives the power available from steam-process reductions for process use at various turbine-inlet pressures and various extraction pressures. This chart is valuable for making preliminary estimates of power possibilities.

There are many schemes of connecting equipment and apparatus for the generation of by-product power from steam used later for process and heating. Figure 13-32 shows an arrangement of a turbine expanding some steam from boiler pressure to a process bleed point and the remainder passing through the lower stages of the turbine to the condenser. Figure 13-33 shows an arrangement using high-pressure boilers which supply two high-pressure turbines; one high-pressure turbine exhausts to a low-pressure condensing turbine and the second to an evaporator supplying the process steam.

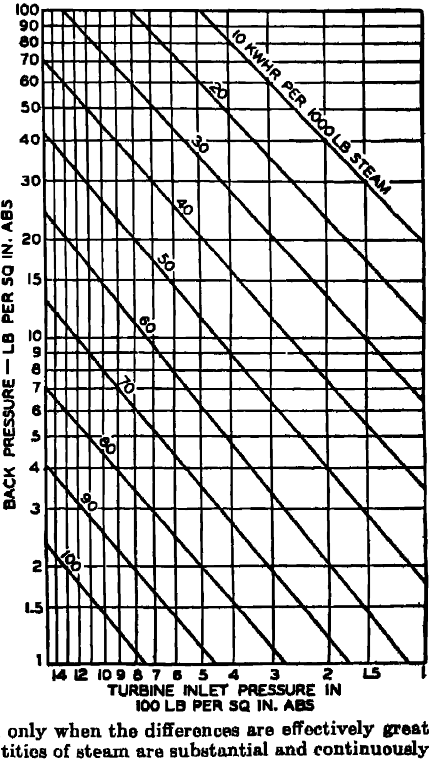

Fig. 13-31. Power available from steam-process reductions for process use. Graph is laid out for 100 per cent turbine efficiency so that conversion may be direct for substantial quantities. Actual yield in power may be taken at 70 per cent of that for the ranges plotted. Pressures are shown in pounds absolute (14.7 lb higher than plus gauge pressures). Following vertically from any generated pressure and horizontally from any exhaust or process pressure, the axis will intersect at a value indicating the kilowatthours that would be produced by passing 1,000 lb of steam from the generated pressure to the pressure used in the process. These values are plotted for a fixed superheat of 150°F above the temperature at the generated pressure. Superheat variation has a very marked effect on the available power. The graph, however, is useful for preliminary estimates of power possibilities, as the curves permit approximation from figures on steam-pressure drop.

Example: Dissimilarity of conditions will produce identical yields in power per unit weight of steam passed. On the curve for 40 kwhr per 1,000 lb, note that this power will be produced by from 375 lb to absolute, and also the same production is possible from passing from 1,200 to 55 lb. "By-product" power from pressure differences is practical only when the differences are effectively great as shown by the curves, and when the quantities of steam are substantial and continuously used.

Commercial development of high-pressure steam (1,000 lb and above) has opened a field of unlimited possibilities in the direct application to chemical processes, but possibly greater possibilities in the field of power generation from steam later bled off or exhausted for process use at moderate pressures.

An approach to the application of steam for both by-product generation and process use would be for the chemical engineers, who are familiar with the process requirements, to set the process pressure or pressures as low as possible for economical production and compile daily load curves for process-steam and power demand. In the design of plants to supply process steam and power simultaneously, this factor of relative amounts of process heat and power required is one of considerable economic influence. For each particular plant, this ratio of steam requirements to power requirements has certain determinable limits. The power engineer, by proper consideration of these limitations with other economic conditions, could assume an initial pressure and plot from the process-demand curve a curve of the by-product power available. The latter curve then could be compared with the power requirements, and if found insufficient at all hours during the day, the boiler pressure may be increased, or the temperature of the steam generated may be increased without change in pressure, or both the temperature and pressure of the turbine-thrott steam may be changed, until the electric power made available by by-product generation would balance that needed. The most effective way of all to increase the power output is to decrease the exhaust pressure.

In actual practice, it may be more economical not to carry the pressure to a point where all the power required can be generated as a by-product of process steam. The propinquity of a central station and a connection with a utility system is a good thing as a stand-by and to take peak loads in excess of power generated. Unfortunately, utility companies by their demand charges under stand-by conditions tend to make such connections unprofitable.

Power Factor

Most industrial-plant power is supplied by a-c systems. Entering into practically all considerations of a-c machinery and circuits is the term power factor, the factor by which volt-amperes must be multiplied in order to find actual power in watts. The over-all power factor of industrial plants is almost invariably lagging. This is principally due to the fact that the major part of industrial equipment operates at lagging power factor. The power factor of typical a-c loads is given in Table 13-17.

In the case of induction motors, the power factor not only varies with the horsepower and synchronous speeds of the motors but also with the loads on the motors. How the power factor of a typical 20-hp 900-rpm induction motor varies with load is shown in Fig. 13-34.

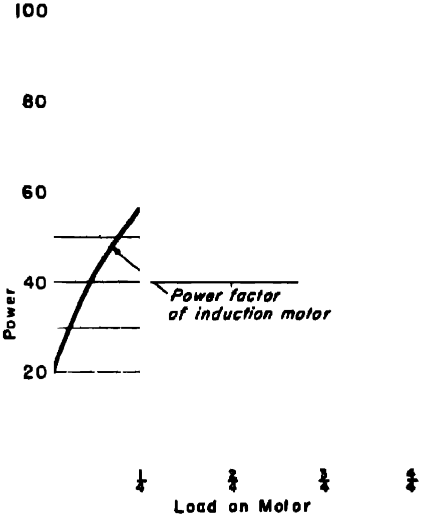

Fig. 13-34. Power factor of a typical 20-hp, 900-rpm induction motor.

Disadvantages of Low Power Factor. Low power factor is detrimental for four important reasons:

1. It prevents the full utilization of the generation and distribution system. The ratings of generators, transformers, transmission lines, feeders, and switches are limited by their current-carrying capacity, and the maximum power (kilowatts) which they may carry is proportional to the power factor. Thus capital investment per kilowatt of load increases as the power factor decreases.

2. It makes each kilowatt of power carry a higher burden of line losses. The resistance losses, being proportional to the square of the current (I^2R), vary inversely as the square of the power factor. Losses are therefore equivalent to an increase in the kilowatt load and increase the cost of delivering power to the utilization equipment.

3. It may cause an excessive voltage drop at the power-utilization equipment and may possibly affect production by reducing starting torque in motors, causing subnormal lighting, and slowing up the operation of heaters.

4. It may increase the purchased-power cost because of power-factor penalties. The detrimental effects of low power factor make it necessary for utilities to incorporate power-factor clauses in rate schedules. The power customer benefits by substantial power-bill reductions when he keeps the power factor of his plant high.

Table 13-18 shows a tabulation of the reactive factor, the ratio of reactive factor to the power factor, and the conductor requirements in per cent for various power factors. Table 13-19 shows a tabulation of the corrective kva requirements for improvement of power factor.

Methods of Improving Power Factor. High power factor is achieved by making the ratio between the kilowatts and kva of the a-c circuits as nearly 1:1 as possible. Several means are available for improving the power factor of an industrial plant. The following are the most important:

1. Minimize reactive kva component. This is a preventive method, such as avoiding oversize or low-speed induction motors and keeping induction motors as fully loaded as possible.

Table 13-17. Power Factor of Typical A-c Loads

Unity (or near unity) power factor		Lagging power factor		Leading power factor	
Load	Approximate power factor	Load	Approximate power factor	Load	Approximate power factor
Incandescent lamps (Power factor of lamp circuits operating off stepdown transformers will be somewhat below unity)	1.0	Induction motors (at rated load)		Synchronous motors (Leading power factor depending on the rated leading power factor for which they are built)	0.9 0.8, 0.7 0.6 etc
Fluorescent lamps (with built in capacitor)	0.95–0.97	Split-phase below 1 hp	0.55–0.75	Synchronous condensers	Nearly zero leading power factor (Output practically all leading reactive kva)
Resistor heating apparatus	1.0	Split phase 1 to 10 hp	0.75–0.85	Capacitors	Zero leading power factor (Output practically all leading reactive kva)
Synchronous motors (Operate at leading power factor at part loads also built for leading power factor operation	1.0	Polyphase squirrel cage			
Rotary converters	1.0	High speed 1 to 10 hp	0.75–0.90		
		High speed 10 hp and larger	0.85–0.92		
		Low speed	0.70–0.85		
		Wound rotor	0.80–0.90		
		Groups of induction motors	0.50–0.85		
		Welders motor generator type	0.50–0.60		
		Transformer type	0.50–0.70		
		Arc furnaces	0.80–0.90		
		Induction furnaces	0.60–0.70		

2. Eliminate lagging reactive kva. Many motor drives permit the use of synchronous motors which require no reactive kva from the line.

3. Offset lagging reactive kva with leading reactive kva, by using (a) leading-power-factor synchronous motors, (b) capacitors, and (c) synchronous condensers.

Figure 13-35 is a diagram showing the typical methods of applying power-factor-improvement equipment. Not all the equipment shown or the specific methods will necessarily be used in any one given plant. As shown in the figure and indicated above, the principal types of apparatus used to effect power-factor improvement are (1) induction motors properly selected to avoid oversizing, (2) synchronous motors for medium and large constant-duty drives, (3) capacitor units, and (4) synchronous condensers.

Induction Motors Properly Selected to Avoid Oversizing. The magnetizing kva of induction motors remains almost constant from full load to no load, while the kilowatts vary with the load.

Thus at light loads the motor input is largely reactive kva, and hence power factor is low.

Obviously then, any practical steps that will result in maintaining as near as possible full-load conditions will be beneficial from the power-factor standpoint. Observing these general rules will help:

1. Care in selection of motors for their jobs. For example, use of high-slip motors for punch presses will usually enable use of smaller horsepower rating than where normal-torque motors are applied.

2 Rearrangement of induction motors in the plant, where practical, to secure over-all average higher loading.

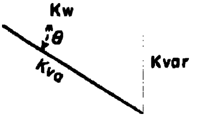
3. Use of wound-rotor induction motor where high starting torque requires oversize squirrel-cage motor.

4. Avoidance of slow-speed induction motors, which have inherently low power factor even at full load in favor of synchronous motors.

The possibility of improving power factor by the proper selection of induction motors should be given greatest consideration at the time of the original installation of these motors. After the motors are installed, it seldom pays to purchase new motors of a different type or rating or to switch motors from one machine to another, except in the larger horsepower sizes, say, over 75 hp. In the case of small motors, the cost of the changes, including changing the foundations, etc., makes the cost per reactive kva gained quite high. Less expensive means, e.g., the use of capacitors, can usually be found for obtaining the same power-factor improvement.

Table 13-18. Power Factor, Reactive Factor, and Variation of Conductor Requirements

Power factor	Reactive factor	Reactive factor, power factor	Conductor requirements, per cent
100	0	0	100
95	0.312	0.329	111
90	0.436	0.482	124
85	0.527	0.620	135
80	0.600	0.750	156
75	0.661	0.882	178
70	0.714	1.020	204
65	0.760	1.170	237
60	0.800	1.333	278
55	0.835	1.519	330
50	0.886	1.732	400



Trigometric relations
Cos θ = power factor
Sin θ = reactive factor
Tan θ = reactive factor/power factor

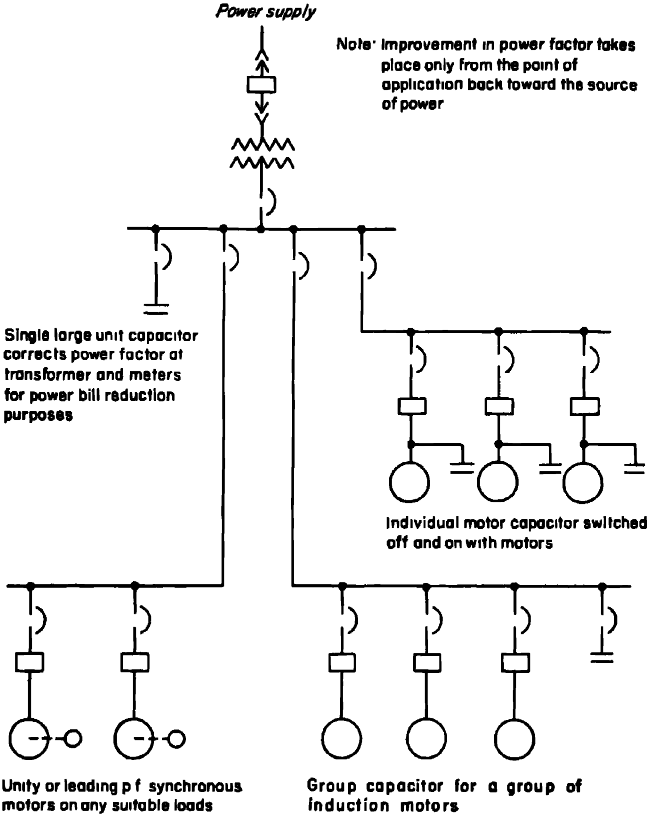
Table 13-19. Corrective Kva Requirements

Original power factor	Final power factor	Per cent corrective kva required
50	55	21.2
55	60	18.6
60	65	16.3
65	70	15.0
70	75	13.8
75	80	13.2
80	85	13.0
85	90	13.6
90	95	15.5
95	100	32.9

Corrective kva in the above amounts would be required to raise the power factor from the original in Col. 1 to the final in Col 2. For example, to raise the power factor of a 1,000-kw load from 75 to 90 per cent would require

1,000 × (0.132 + 0.130 + 0.136) = 398 kva.

Synchronous Motors for Medium and Large Constant-duty Drives. Synchronous motors are standard drives for the larger compressors, pumps, fans, blowers, crushers, grinders, line shafts, motor-generator sets, and for mills and rolls in cement, rubber, metal, mining, pulp and paper, flour milling, and other plants. Wherever there are suitable drives in the plant, synchronous motors may be advantageously used for they perform the double duty of driving the load and improving the power factor at a very low unit cost. There are two types of synchronous motors, unity power factor and leading power factor.



Power supply
Note: Improvement in power factor takes place only from the point of application back toward the source of power
Single large unit capacitor corrects power factor at transformer and meters for power bill reduction purposes
Individual motor capacitor switched off and on with motors
Unity or leading p f synchronous motors on any suitable loads
Group capacitor for a group of induction motors

FIG. 13-35. Principal types of apparatus used to effect power-factor improvement in industrial plants.

A unity-power-factor synchronous motor operating at full load does not actually deliver any leading kva to the system, but its substitution for a lagging-power-factor induction motor or its addition to a load whose power factor is already lagging obviously increases the ratio of kilowatts to reactive kva and thereby improves the power factor.

A leading-power-factor synchronous motor will deliver leading kva proportiona to input power, which depends on the horsepower delivered, and proportional to the ratio of input reactive kva to input kilowatt power, this ratio depending upon the power factor.

The curves of Fig. 13-36 show the approximate leading kva drawn by synchronous motors operating at partial loads with full-load excitation maintained. When operating at partial load, a synchronous motor will deliver more leading kva than when operating at full load. This is a result of the lower reactance drop in the machine at light loads. Note that unity-power-factor synchronous motors operating at partial load may actually draw a leading kva.

The principal advantage of the use of synchronous motors to improve power factor is that, over a large range of horsepowers and speeds, particularly above 100 hp, synchronous motors provide leading kva at a very low cost. For motors of several hundred horsepower, this cost reaches a value as low as $1 per kva gained by the use of a synchronous motor instead of an induction motor. There is no other available equipment that has such a low initial cost per unit leading kva furnished.

The principal disadvantage, or rather limitation, in the use of synchronous motors for power-factor improvement is that it is economical only for a more or less constant-duty constant-speed motor of moderate or large size when such is required for a plant drive. The cost per kva correction gained in the small-horsepower ratings is high—about $20 for each reactive kva gained using a 50-hp 80 per cent power factor 1800-rpm synchronous motor.

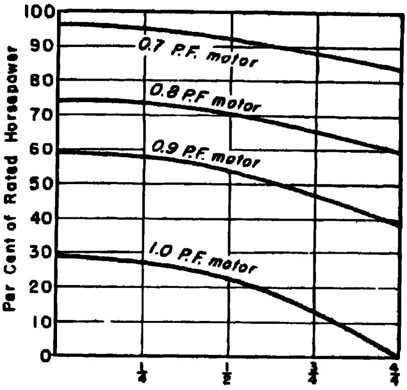


FIG. 13-36. Approximate leading kva in per cent of rated horsepower of motor that will be supplied by synchronous motors operating at various loads under full-load excitation.

Also, in general, synchronous motors are usually economical only for application to new drives. The advantage in low cost per kva gain which is obtained by using synchronous motors is generally lost if the motor is to be substituted in place of an induction motor already installed.

Where there are no suitable drives for synchronous motor applications and when a completed plant requires power-factor correction, it is usually necessary to resort to capacitors.

Capacitor Units. Capacitors are stationary devices, the sole function of which is to deliver leading reactive kva for the magnetizing requirements of induction motors and other induction equipment on the plant system. These units deliver leading kva proportional to the square of the impressed voltage and inversely proportional to their reactance.

Advantages of capacitors include the following: (1) being static devices, they require little attention for maintenance or operation; (2) they can be installed in convenient locations within the plant without disturbance to production at reasonably low installation charges; (3) installation may be made at any time the power-factor conditions warrant and in a wide variety of capacities to fit the power-factor requirements of circuits or individual motors; (4) losses are low—one-sixth to one-fourth of 1 per cent of the kva rating.

The initial cost of capacitor units per leading kva is fairly high as compared with the cost per kva of synchronous motors or synchronous condensers. The use of capacitors for power-factor improvement is most economical under certain conditions. Installed cost of 460-volt capacitors averages about $10 per kva with 230-volt units costing about twice as much. Other voltages and ratings vary from $10 to $15 per kva. The reason for the higher cost of the low-voltage capacitors is that the capacity required, as noted above, varies inversely as the square of the voltage, and at low voltage, about 460 volts, the thickness of insulation can no longer be reduced with the result that it is necessary to increase the size of the unit in order to obtain the capacity for the lower voltage. Ratings of capacitors are proportional to the frequency, and this makes the use of capacitors extremely high for installation on 25-cycle systems.

Synchronous Condensers. A synchronous condenser is similar to a synchronous motor, built primarily, however, to operate without mechanical load and to correct power factor or regulate voltage by drawing a lagging current component from or supplying a leading current component to the power system.

The cost of synchronous condensers is considerably less than that of capacitors, particularly in the larger sizes. The cost varies between $5 per kva (5,000-kva rating) to about $10 per kva (500-kva rating). They are seldom found to be economical in sizes below 500 kva and for this reason are seldom used in industrial plants.

Synchronous condensers are used particularly by power companies, where very large amounts of leading reactive kilovolt-ampere component are required and where regulation of voltage, by changing the condenser excitation, is desirable.

Amount of Investment Justified for Power-factor Improvement. Most purchased power schedules contain power factor clauses resulting in the adjustment of billing demand based on average power factor. The essential items of a typical utility's company rate schedule are as shown in Table 13-20.

Table 13-20

Demand charges		Energy charges	
First 100 kw of BD	$2.15/kw	First 5,000 kwhr	1.6¢/kwhr
Next 100 kw of BD .	1.65/kw	Next 100 hr or BD	0.9¢/kwhr
All over 200 kw of BD	1.40/kw	Next 200 hr of BD	0.7¢/kwhr
		Excess	0.6¢/kwhr

BD = billing demand = (90/pf) × metered demand

The monthly power bill under the above rate may be set in a formula as follows if the demand is over 200 kw and the kwhr use reaches into the 0.6¢ per kwhr rate.

$$\text{Power bill/month} = \$200 + \$1.9\ [90/\text{power factor} \times \text{demand}] + \$0.006 \times \text{kwhr}$$

The factor $1.9 [90/power factor × demand] is the only factor affected by power factor and is the only item necessary to consider for the following example:

Assume we have four 500-kva 4,160/480-volt substations at a plant supplying associated feeders fully loaded for the demand periods and operating with a high ratio of average load per maximum demand at a monthly power factor of 85 per cent. The metered demand would be 1,700 kw and the billing demand, 1,802 kw, at a monthly cost of $3,423.80.

The addition of 495 kva of capacitors would improve the power factor to approximately 95 per cent at an estimated total installed cost of $5,000 for 33, 15-kva 460-volt capacitor units and associated equipment. The metered demand would be the same as before (1,700 kw), but the billing demand would be reduced to 1,611 kw at a monthly cost of $3,160.90, or a saving of $262.90 per month.

Thus, the investment required for the 495 kva in capacitors would pay for itself in 19 to 20 months through savings in the power bill.

In addition, the installation of the capacitors has made available 200 kva extra capacity in transformers and main feeders plus the voltage improvement. This is the reason capacitor units can sometimes be justified on plants generating power locally. In the above example, 200 kva of generator, transformer, and feeder capacity is obtained at a cost of $5,000, or at the rate of $25 per kva.

Such economies as these are not out of the question. It is not economical to improve the power factor much above 95 per cent because of the large amount of capacity in corrective kva required for the gain. In plants that undergo rapidly changing methods and fluctuations in production, the investment for power-factor correction is expected to pay for itself in 2 years. In stable industries, large office buildings, public institutions, etc., which expect to operate in the similar manner for a number of years, an investment would be considered satisfactory if it paid for itself in 4 or 5 years.

Sometimes switching is necessary to keep light-load voltages within acceptable limits. If automatic means of switching is provided this would increase the cost of a capacitor bank $2 or $3 per kva.

The modern capacitor's reliability, relative cost level, and flexibility have resulted in one of the most economic tools that is now available to the industrial electrical engineer. However, it should be noted that most power-factor clauses in utility companies' schedules are based on average power factor. For this reason there is usually a certain point beyond which it does not pay to use capacitors to improve power factor alone. For example, a majority of industrial plants have a high kilowatt load during the main working shift and possibly a load of one-quarter or less during the remainder of the day. If capacitor units were installed to correct for a high power factor at peak load, they would be effective only part of the time (reactive kva meters are provided with a ratchet arrangement which prevents them from running backward in case of leading kva). For this type of plant, it would be necessary to plot a graph of the reactive kva load-time curve to determine the maximum kva of capacitors which would be economical to install. Any further improvement in power factor desired should be obtained by the use of a synchronous motor or possibly a condenser, since its cost per kva is much less and would probably be operated only during high load periods.

In order to obtain the most satisfactory and economical means of power-factor improvement, it is necessary to (1) make a system survey of load and power factor and compare with a log of plant operations; (2) check possibility of reducing demand peaks; (3) rearrange large motors, if practical, so they will operate at or near full load; (4) formulate a decision on the type of equipment and arrangement that will best serve the plant requirements (see Fig. 13-35).

PART 2. INDUSTRIAL-PLANT LIGHTING

Satisfactory industrial-plant lighting can be obtained only through intelligent engineering. Lighting is complicated by a diversity of many possible light sources, a variety of fixtures, and equipment arrangement. Engineering is more needed now than ever before so that advantage may be taken in selecting the best for each application. To provide satisfactory industrial-plant lighting it is necessary not only to have an intimate knowledge of the illumination problems but also of process requirements.

Eyesight conservation is concerned not only with proper lighting to aid human eyes to perform seeing tasks without undue eyestrain and fatigue but also with the care of eyes through medication and eyeglass correction if necessary. Before discussing the actual mechanisms of a satisfactory lighting installation, it is most desirable to review briefly the fundamental principles of the characteristics of light and its action on the eyes. For proper seeing, these two items are of great importance. Some understanding of the influence of lighting upon visibility, the ease of seeing, and the relationship of lighting to ease of seeing are essential factors in judging the results obtained with artificial illumination.

Light, vision, and seeing are commonplace, but the effects of seeing extend far beyond the eyes into the realm of human beings, eventually affecting their behavior and finally their efficiency and welfare. This is not an accident. It is due to the fact that lighting is a part of so much of our daily routine activities.

The importance of light, vision, and seeing cannot be overestimated. The success of most industrial occupations depends upon man's mind aided by his five senses: sight, hearing, touch, taste, and smell. Of these senses, sight is by far the most educative, educated, and useful sense. It is responsible for 75 to 90 per cent of the usefulness of most civilized adults. The industrial worker's efficiency is, therefore, greatly affected by the lighting conditions under which he works. In addition, good seeing conditions have a dual significance to good workmanship since they affect, directly, the particular job being done and, indirectly, the workman's entire attitude toward the job. This results in better health conditions, less labor turnover, fewer accidents, and decreased material spoilage.

Because adequate lighting can contribute much to efficient production, lighting is now accorded a much more important place in production than ever before in our industrial history.

After defining some of the more common illumination terms, the important items that must be considered in planning a lighting layout will be discussed.

Definition of Common Illumination Terms

As in the gradual development of any science or work, a pertinent phraseology has grown with the science of illumination. Certain of these terms will be used in subsequent discussion. Listed below are the more common terms used, together with their definitions.

Absorption. A certain amount of the light which hits an object is absorbed by that object. The amount absorbed depends upon the reflection factor of the surface.

Brightness. The brightness of an object depends upon the intensity of the illumination on it and the percentage of light it reflects, emits, or transmits. Brightness is one of the fundamental factors in seeing. When brightness values are low, seeing becomes difficult and slow. Extremely high brightness or wide variation in brightness in the visual field can cause glare and eye fatigue.

Diffusion. Many surfaces, such as plaster and opal or prismatic glass, break up the incident light from a point source and distribute it more or less over an entire surface. Diffusion tends to enlarge the image of light source and reduces its brightness by breaking up its outline. Glare is, therefore, reduced, and seeing becomes easier.

Fluorescent. Fluorescent lamps are electric-discharge lamps in which the radiant energy from an electric discharge is transferred by suitable material (phosphors) into wave lengths giving higher luminosity

Filament. Filament lamps are light sources that consist of glass bulbs containing a coiled filament electrically maintained at incandescence by heat energy created by the electric current.

Foot-candles. A foot-candle is the measure of illumination on a surface which is 1 ft distant from, and perpendicular to, a source of illumination of 1 candlepower. This is the term used to determine the illumination on a working surface.

Foot-lambert. A foot-lambert is a measure of brightness. Numerically, it is approximately equal to the product of the incident foot-candles and the reflection factor of the surface, the degree of brilliancy of any part of a surface or medium of transmitting light.

Glare. Glare may be defined as brightness out of place. The degree of brilliancy of any part of a surface or light source, when viewed from a designated direction, determines the amount of glare. Glare may be direct or reflected from any surface and is injurious to the eye.

Illumination. Illumination may be termed the effect or result of light.

Incandescent. See *Filament.*

Light. For the purpose of illumination engineering, light is radiant energy evaluated according to its capacity to produce visual sensation.

Lumen. A lumen is the unit of light flux representing a quantity of light. One lumen is the total amount of light falling upon 1 sq ft of surface, every part of which is 1 ft distant from a point source of 1 candlepower.

Luminaire. Luminaire is a term broadly used in industry to designate any type of lighting fixture, complete with globe, reflector, refractor, and housing.

A luminaire designed to distribute 90 per cent or more of its light output downward below the horizontal is classed as *direct*

A luminaire designed to distribute from 90 to 100 per cent of its light output upward above the horizontal is classed as *indirect.*

A luminaire designed to distribute from 60 to 90 per cent of its light output downward below the horizontal and from 10 to 40 per cent of its light output upward above the horizontal is classed as *semidirect.*

A luminaire designed to distribute from 40 to 60 per cent of its light output upward above the horizontal and the balance downward is classed as *direct-indirect.*

A luminaire designed to distribute from 60 to 90 per cent of its light output above the horizontal and 10 to 40 per cent of its light output below the horizontal is classed as *semi-indirect.*

Mat Finish. Mat finish is a dull finish opposite that of specular. Light hitting a mat finish has a minimum of reflected glare.

Mazda. Mazda is a trade name formerly used by General Electric and Westinghouse for most lamp bulbs made by them, both incandescent and fluorescent. The term is taken from the Persian word meaning "God of Light."

Reflection. Light is reflected from any given surface, depending on its finish. The ratio of the reflected light to the incident light is termed "reflection factor." A bright, shiny piece of metal, for example, will reflect much more light than a dark, dull piece of fabric.

Refraction. Light in passing from one medium to another passes through the second medium at an oblique angle and might be referred to as "bent" light.

Specular Surface. A specular surface is a bright, shiny surface, opposite that of mat finish. Light hitting a specular surface is reflected therefrom at an angle equal to the angle of incidence. The light reflected from a specular surface is usually very bright and has much glare.

Surface Brightness. Surface brightness is the degree of brilliancy or luminous intensity of any part of a surface when viewed from a designated direction.

Transmission. Transmission describes light going through a transparent or translucent medium. The ratio of light transmitted to the incident light is termed "transmission factor."

Watt. A watt is a unit of electrical power in which all lamp bulbs are rated.

Characteristics of Light

Both light and vision are essential for seeing. They may be considered as a partnership in which one is essential to the usefulness of the other.

Light is a form of radiant energy which is transmitted as a transverse wave motion from the source to the receiver and travels through space in the form of electromagnetic waves similar to radio, X-rays, and gamma rays. All electromagnetic radiations have a common characteristic in that they are propagated through space at the same rate. The only difference is in the wave lengths. The visible octave is only a small portion of the energy emitted by the light sources or sent out by glowing solids.

Figure 13-37 is a graph of the electromagnetic spectrum and shows the waves which manifest themselves in a variety of ways as noted above, depending upon their wavelength characteristics. Because seeing results only when radiant energy within the limits of the visible spectrum enters the eye, it is interesting to note the extremely limited range associated with vision. Some rays do not react upon the eye at all, and others are transformed into heat which may irritate the eye. Even in the visible ranges, the average observer will find that the colors in the spectrum of sunlight do not appear to be of equal brightness even though they may reach the eye with equal intensity

Figure 13-38 shows a curve indicating the degree of eye sensitivity to the various wavelengths of visible light. Those in the center portion of the visible spectrum provide normal high visual sensation Tests indicate that the yellow-green light of 5550Å has the greatest brightness If the visibility for this wavelength is designated a 100 per cent relative response, the curve represents the respective visibility with the other specular colors expressed in percentages of this wavelength. The curve is based on the average levels for daylight vision with the cones of the retina of the eye chiefly concerned in the seeing process.

At very low levels of illumination, approaching moonlight, only the rods of the eye are involved, and the eye-sensitivity curve will no longer have a peak at 5550Å. The whole curve shifts toward the blue part of the spectrum by about 480Å or to 5070Å. The wavelengths at this low level are seen as colorless only, those at the blue end of the spectrum appearing brighter than those at the red. This has proved important in installations involving very low levels, such as those required for "blackout" purposes. The eye is, therefore, capable of adapting itself under illumination values which range from a fraction of a foot-candle to several thousand. As mentioned before, the eye be 7,000 ft-c from the sun and 1,000 ft-c from the vault of the sky—a total of 8,000 ft-c. The horizontal intensity at the eye level will be about 1,000 ft-c. The light in the shade of a tree will be 300 to 500 ft-c.

2. Average daylight appears practically white or colorless. Skylight is definitely bluish because of the scattered rays of sunlight.

3. Daylight varies greatly in spectral character with the time of day and with the point of the compass. It ranges from one extreme, a combination of direct and indirect lighting on sunny days, to totally indirect lighting when the sky is completely overcast.

4. Direct sunlight has in December less than half the light value that it has in June.

5. On the average, in the United States, about one-third of the daylight hours throughout the year are cloudy. The sun shines an average of only five hours per day during the months of December and January.

6. The seeing conditions outdoors are the result of the brightness level and the distribution of brightness and color. The same seeing conditions can be produced indoors with artificial lighting, the chief difficulty being to supply the high level of illumination required to produce the necessary brightness of low-reflection-factor surfaces.

Action of the Eye

To understand the relationship of light to sight and its final result, seeing, some knowledge of the structure of the eye is needed, not necessarily knowledge of the disorders of the eye and visual nervous system but rather of the mind's ability to see as related to the character of the lighting.

The eye is one of the most delicate and miraculous organs in the human body. It is most frequently compared with a camera having compound lens (the cornea and lens of the eye combine to focus the light), a shutter (the iris), a black box (the eyeball), and a photographic plate (the retina) on which the pictures are recorded.

Paradoxically, we do not see with our eyes at all but with our brains. The image on the retina is the picture that the mind sees. Seeing is one-half physical and one-half mental. It is, therefore, more accurate to compare the eye with a television camera, for it takes light waves and transmits them to electric waves which become images. The eye is merely the device which turns light into the little electric current that the brain sorts to the ordered images we see. Without the brain or the optic nerve, the image on the retina is as useless as an undeveloped film.

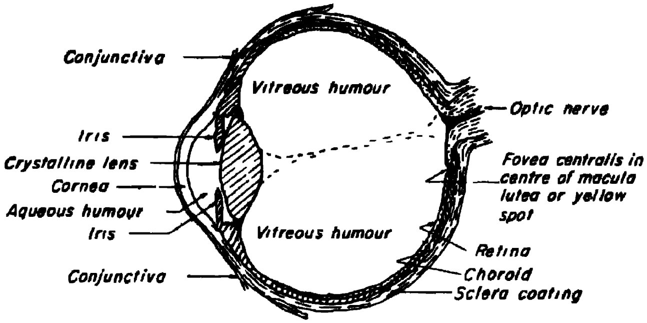
The process by which the eye is capable of receiving impressions from waves of light and passing them on through the optic nerve to the nerve cells in a definite area of the cortex of the brain remains one of the mysteries of the human body.

The eye itself is a globe composed of three layers of membrane called the sclera, the chorioid, and the retina. The eye is divided front and back into two chambers. In the front chamber are the crystalline lens, the iris (in the center of which is the pupil), the aqueous humor (a clear waterlike fluid), and the cornea. The posterior chamber is filled with a semifluid, semijelly substance, called the "vitreous humor." The inner lining of this chamber is the retina, and the back of the retina is the layer of pigment which gives the eye its color. Figure 13-39 shows a cross section of the eyeball and the position of the various elements of the eye.

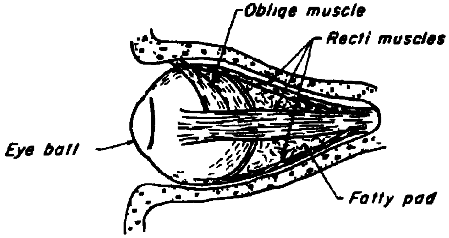
The eyeball is positioned in a bony depression of the skull which affords it much protection. The depression immediately back of the eye is filled with fat, giving the eye a cushion on which to turn. The eye can be moved in all directions by muscles attached to the eyeball and the bony socket. The exposed surface of the eye is covered by a highly sensitive membrane, the conjunctiva. The eyelids, which are quick-acting shutters ready to protect the eyes, are also lined with conjunctiva. The circular shutter over the lens, the iris, closes in over the lens in response to a strong light and to messages sent along a nerve.

All these mechanisms are a great protection to the delicate organ, but, in spite of these precautionary features, disease, deformity, and sometimes merely the strain of civilized activities hurt the eyes and reduce the efficiency of living. Inadequate food and air are quite immediately obvious in their effects, but this is not true with light and vision, since the eyes are much more patient and less complaining than the lungs or stomach. The correct principles of eye health are deeply rooted and fixed by nature, and anything that affects the general health of a person can't fail to have an effect upon his eyes. Most persons refuse to take as good care of their eyes as they do of their digestive systems. They suffer eyestrain without always knowing it and rebel at the suggestion that something else beside the lighting is the cause of the complaint.

The eye is admirably equipped to protect itself and function under widely varying light conditions. However, the prolonged use of the eyes at work, at home, or at play, under inadequate or glaring lights, leads to a strain on the physical reactions that can seriously affect the worker's health and well-being. Under proper lighting conditions the normal eye may see without strain. It is, therefore, the obligation of the lighting engineer to determine proper light sources, favorable lighting conditions, and adequate light intensities that are necessary to meet satisfactorily the requirements for the various visual tasks encountered in industry.



Cross-section of the human eye



Muscular attachments of the eyeball

FIG. 13-39. Cross section and muscular attachments of eye.

Eyestrain arises through muscular and not retinal activity. Low illumination levels or poor lighting conditions will result in poor visual acuity, and the balance between accommodation and convergence is likely to be disturbed. The efficiency of the eyes depends on their freedom from errors of refraction, defects of fixation, and the transparency of the cornea.

The first steps in reaching right seeing conditions are

1. Have the eyes of all employees examined at biennial intervals in order that refractive changes within the eye may be discovered and corrected before serious eyestrain develops.

2. Recommend that all employees who have visual defects be equipped with proper corrective lenses.

Some rules for eyesight conservation of actual preventive values, such as means of giving respite for near vision, good lighting, eye exercises, and generally better seeing conditions, will be discussed under Illumination Yardsticks.

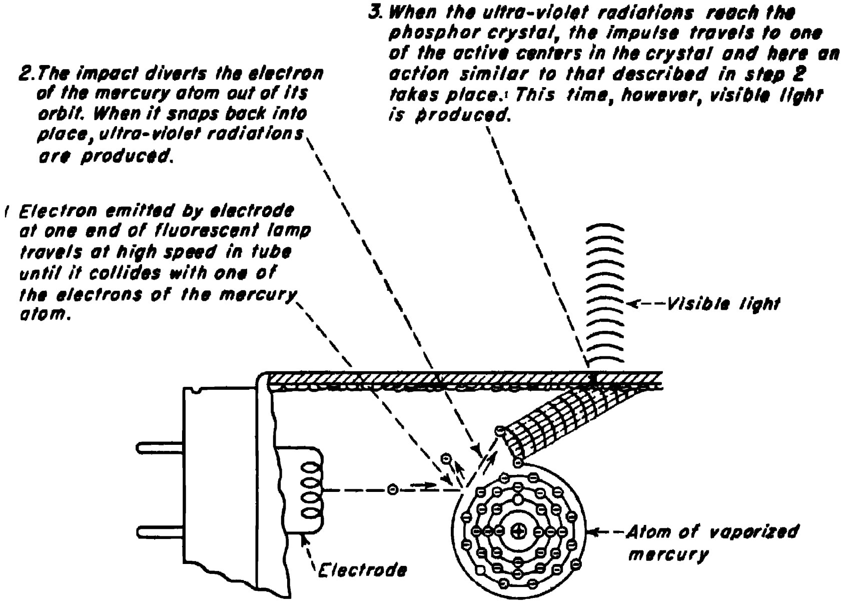
The most important facts concerning vision are enumerated below:

1. Relaxation is very closely associated with vision. It is estimated that the lack of relaxation is the cause of 80 per cent of defective sight. Tension of any kind blurs the brain and pulls the eyes out of focus.
2. About 82 per cent of all persons in this country over 50 years of age have defective vision.
3. Fifty million people in the United States either wear glasses all or part of the time or, in the opinion of eye physicians, need to wear them.
4. The eyeball is held forward in position by a fatty pad and can be operated in any direction by six muscles.
5. Four of the six muscles (known as recti muscles) are evenly spaced around the eyeball and pass directly back of the cavity.
6. The two remaining (oblique) muscles, which pass partly around the eyeball, then through a ligamentous loop before going back to the cavity, give the eye power to see at varying distances by squeezing the eye and changing the balance of pressure within the eyeball.
7. When the oblique muscles are tightened, the eyeball is elongated. When the recti muscles are tightened, the eyeball is shortened and thickened. This changing balance gives us our change of focus, the former when the eye focuses for the near point, as in reading.
8. The normal human eye forms without effort clear images of objects 18 or more feet away. Closer objects require accommodation by the recti muscles. The extrinsic muscles of the eye are means of accommodation. It is when these muscles tighten into habitual tension that eye trouble develops.
9. Eyestrain is the cause of impaired sight, not the result of it. Strain is caused frequently by improper lighting conditions. However, other circumstances result in improper use of the eyes and produce eyestrain.
10. The retina has two distinct types of vision: (*a*) central or the positive, clear vision only in the exceedingly small area in the center of eye; (*b*) collateral, or vision only to the extent of general form, general motion, and color which is progressively reduced beginning at the center of the retina outward until at the periphery it is very poor.
11. The eye sees only while it is at rest. There are no "sweeping glances" so frequently mentioned. The eyes do not move continuously, but in little jerks, jumping from point to point.
12. Our usual appreciation of the solidity of objects is due to the cooperation of both eyes. Each eye, taken separately, yields a slightly different impression, but the two impressions together combine to show what is known as "stereoscopic effect," a three-dimensional effect.

Comparison of Light Sources

Within the past few years we have witnessed a phenomenal increase in the multiplicity of light sources and control materials. Twelve years ago there were only two common light sources available: the incandescent tungsten-filament lamp and the Cooper-Hewitt mercury lamp. Newer light sources now include hot- and cold-cathode fluorescent, high-intensity mercury-vapor, and sodium-vapor lamps. All the newer sources have longer life and deliver more lumens per watt.

The choice of the light source to be used in a lighting installation deserves as much consideration as the choice of any of the other tools used in industry. The use of any light source is to convert electrical energy into light for the purpose of making the process of seeing easier and more comfortable. The possibility of carrying on work in industrial interiors depends upon lamp performance based on three factors: light, life, and uniformity. The economic factors involved in lighting will be discussed farther on in this subsection. At this point it is sufficient to state that the cost of power consumed during the life of a lamp is, in almost all cases and particularly in the case of the incandescent lamp, many times the cost of the lamp itself. Furthermore, it must be borne in mind that lamp life and light are interdependent. If the quality of light given by more than one type of lamp is considered to be suitable for a given industrial process, the final choice of type should depend on relative costs.



3. When the ultra-violet radiations reach the phosphor crystal, the impulse travels to one of the active centers in the crystal and here an action similar to that described in step 2 takes place. This time, however, visible light is produced.
2. The impact diverts the electron of the mercury atom out of its orbit. When it snaps back into place, ultra-violet radiations are produced.
1 Electron emitted by electrode at one end of fluorescent lamp travels at high speed in tube until it collides with one of the electrons of the mercury atom.

How a Fluorescent Lamp Produces Light

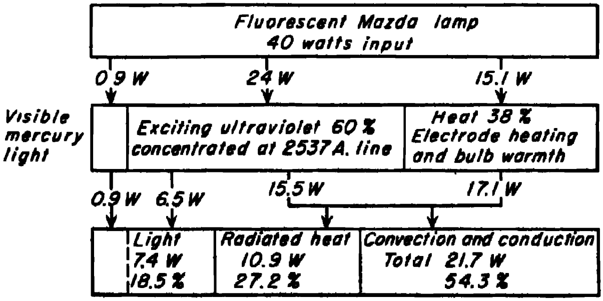

Fig. 13-40. How a fluorescent lamp produces light, and its distribution of energy.

All light sources are generators of radiant energy. As mentioned before, the generation of light has until recently been generally limited to the incandescence of hot solids. Much of the energy radiated by the tungsten filament lies outside the visible octave, and for this reason, it is not very efficient as a light source. The heat losses are on the order of 90 per cent of the total input. For a commercial tungsten 200-watt lamp, the efficiency is but 18 lumens per watt. In the relatively short period of 40 years, we have advanced from a carbon source producing 3.5 lumens per watt to the

Table 13-21. Comparison of Present-day Light Sources

Characteristic	Incandescent	Fluorescent	Mercury vapor
1. Type of source. . .	Point or concentrated	Linear	Point and linear
2. Color quality of light produced	Rich in the yellow and red portions of the spectrum varying from candle-flame yellow to light yellowish white. Also made in colors	Daylight, 4500°K white, white, warm tone, and soft white. Also made in colors: blue, green, pink, gold, and red	Almost a monochromatic light is the blue and green portions of the spectrum, which is particularly well adapted to lighting the neutral tones in metal working
3. Bulb finishes	Clear, inside frosted, white bowl, daylight, silver bowl, silver neck, color coated, and natural colored glass	Daylight, 4500°K white, white, warm tone and soft white. Also made in colors: blue, green, pink, gold, and red	Clear
4. Rated operating life. . .	750 hr up to 150 watts. 1,000 hr over 150 watts. Also special-life lamps	2,500 to 7,500 hr, varying and increasing with longer operating hours per start	2,000 to 4,000 hr, varying and increasing with increased operating hours per start
5. Lamp efficiency . .	10 to 20 lumens per watt, depending on lamp size (average of 15-in. range of 60- to 200-watt sizes)	39 to 62 lumens per watt (not including auxiliaries), with auxiliaries produces about 2 to 3 times as much light per watt as incandescent	30 to 40 lumens per watt (not including auxiliaries)
6. Lamp wattage.	6, $7\frac{1}{2}$, 10, 25, 40, 60, 100, 150, 200, 300, 500, 750, 1,000, 1,500, 2,000 in standard sizes	4, 6, 8, 14, 15, 20, 30, 40, 65, 85. Also Slimline units 18 to 96 watts	100, 250, 400, 1,000 (water-cooled), 3,000
7. Lamp size and shape . .	2- to $6\frac{1}{2}$-in. diam. in tear-drop and pear shape; also short tubular	Tubular $\frac{3}{4}$ to $2\frac{1}{8}$ in., 6 to 96 in. long, circular 25 watts, $1\frac{1}{4}$-in. tube, 12-in. diam	250- and 400-watt short tubular; 3,000-watt long tubular source
8. Relative installed costs for equal lighting intensity 40 to 50 ft-c	100 per cent	165 per cent	180 per cent
9. Relative maintenance costs			
a. Lamp replacements including labor	100	110	105
b. Cleaning and maintenance.	100	300	130
10. Relative power costs	100	40	65
11. Relative cost per foot-candle year.	100	75	85
	(See notes at end of table for basis of comparisons)		
12. Advantages	Availability and convenience. Requires no control gear, ballast, or starters. Light distribution subject to beam or spread control. Starts instantly when turned on. Will withstand repeated starts better than any other source. Can be used in all kinds of weather. Installation costs relatively low	High lumen output per watt. Less heat is obtained. Surface brightness is low. Long lamp life. Lower current consumption for a given light output. More illumination can be obtained from old wiring by a change to fluorescent	High lumen output per watt. Useful for high bay mounting. Light is of particular advantage for critical inspection work. Because of green color, operating cost relatively low
13. Disadvantages.	Color is too rich in the red and yellow. Efficiency per watt is relatively lower than fluo-	Accurate beam control from the tubular lamp is not possible. Requires auxiliary equip-	Color of light is the chief objection to widespread use. Requires auxiliary equip-

	rescent or mercury. Much heat has to be dispersed or dissipated; characteristics of operation are greatly affected by voltage variation from normal rating	ment, ballast, starters, condensers, all of which complicate maintenance and increase weight and bulk of installation. Standard units will not give satisfactory operation in cold or high-temperature locations. If operated with a single lamp ballast, stroboscopic effect may be present. Can be operated on direct-current but at decreased lumen output, lamp life, and starting reliability	ment. Delayed start of 3 to 7 min. Cost of equipment is relatively high

NOTES. Items 8, 9, 10, and 11 are given as a basis of comparison of lighting costs for providing a grade B (40 to 50 ft-c in service) lighting intensity in an area 100 by 100 ft square under the following conditions: complete wiring and conduit installation including incoming line services, transformers, panels, etc ; 500-watt incandescent glassteel diffusers, 150-watt fluorescent RLM reflectors (3 to 40-watt lamps); 250-watt mercury enclosed RLM luminaire; 8 000 hr total operating time per year; 20 per cent annual owning cost per year (5-year amortization). All relative percentage costs are established, using the incandescent system as the base The ratio of relative costs will change for each and every type of installation, depending upon various economic factors and their relative influences. Data based on a composite of plant experience Cost of allocated facilities not included. Electric energy based on purchased cost of $0.01 per kwhr.

40-watt fluorescent lamp thirteen times as efficient. With these illuminants the electric energy is transferred to ultraviolet and visible radiations without incandescence. Figure 13-40 shows how a fluorescent lamp operates and its distribution of energy.

The ultimate efficiency that may be expected for white light is approximately 200 lumens per watt. Figure 13-41 is a graph showing the comparative efficiency of light sources. Today, with gaseous-discharge lamps, we have efficiencies of 40 to 60 lumens per watt. Within the next few years, with new illuminants or high-pressure mercury arcs, the efficiency may advance to 100 lumens per watt.

Intelligent use of light to meet industrial man-power-production requirements calls for an understanding of the characteristics of light sources. Incandescent, fluorescent, and mercury-vapor lamps are briefly appraised and reviewed in Table 13-21 to assist in an understanding of the many opportunities they offer in installing lighting to meet present and future man-power-production requirements.

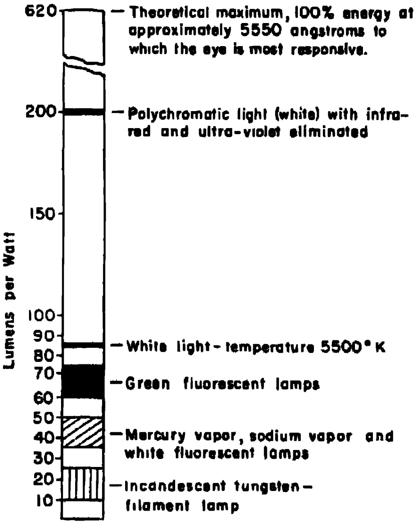

FIG. 13-41. Comparative efficiencies of light sources.

The incandescent filament lamp will always fulfill some purposes better than any other light source. Also, because of economy of installation, flexibility, ease of maintenance, and convenience of lamps and incandescent lighting equipment, it will always have a wide application.

The fluorescent lamp has a much longer life than the incandescent and will provide approximately two to two and one-half times as much light per watt as the latter type. Wartime lighting levels made possible by the use of fluorescent lamps have been carried over into civilian uses. With the return of peace after the Second World War, the range of colors, the quality, and simplification of equipment improved. It is expected that fluorescent lighting will assume the major place in general industrial-plant lighting.

The fluorescent Slimline is the newest lamp development. This lamp is appropriate for any fluorescent lighting installation. Its small diameter makes possible its use in places where space is limited. The 72- and 96-in. lengths give longer lines of light with fewer interruptions, as they are instant-start and have single-pin terminals, which make for simpler wiring. The long lengths help appearance and reduce the number of lamps, sockets, and ballast needed. The current range allows low, medium, or high lamp brightness through the control of current varying from 120 to 600 ma.

The mercury-vapor long has been the most economical light producer. The blue-green color is the chief objection to its widespread use. In many large industries, chiefly metal work, the color has its advantages. Combined with incandescent lamps, the mercury source promises to be more widely used, especially where large areas are to be lighted from high mountings.

For plant road and street lighting, the mercury color is not unlike moonlight, and its high efficiency provides more adequate illumination for the same expenditure. The sodium light will be used as a warning of danger, at heavy-traffic intersections, approaches to bridges, underpasses, and to indicate similar hazards.

Effects of Voltage Regulation on Lamp Operation

Industrial distribution systems and utilization equipment are designed on the basis of a nominal constant voltage. Lamps are designed to give the most economical combination of characteristics at rated voltage. In the case of incandescent lamps, the light output varies directly as the 3.4 power of the rated voltage, and the average life of the lamp varies inversely as about the thirteenth power of the rated voltage.

Fluorescent lamps are not affected so critically by voltage variation as are incandescent lamps. This is one of the advantages of fluorescent-lamp sources. However, undervoltage (below 105 volts for standard lamp) will decrease the light output and result in uncertain starting and operation. Overvoltage (above 125 volts) causes inferior lamp performance and danger of overheating the auxiliaries.

Mercury-vapor lamps are affected in light output very much the same as are incandescent lamps. Abrupt dips in voltage may cause objectionable light flicker in any type of lamp.

The Lighting Source for the Job

Adequate lighting may be provided by incandescent, fluorescent, or mercury-vapor lamps. It is assumed that each of these three types has its specific basic application and that there is one type of lamp best suited to any one job. As a matter of fact, this is seldom the case. More often there are two types of lighting sources each of which may serve equally as well and also some problems that will require the combination of all three sources to provide adequate lighting.

The final choice of a lighting source for any particular application may result from one of the following factors:

1. Some local physical limitation, such as machinery and structural members
2. Some economic factor peculiar to the job
3. Some operating condition, such as gas and explosion hazards, dirt, and corrosive vapors
4. The psychological reactions which different persons have for the effects of the various sources and types of lighting

It may be asked which lamp is best suited for a machine shop. Machine-shop work covers every grade of work from reading the fine calibration on a gauge to the visual task of a crane operator or a welder. Certainly, here are extremes that do not necessarily need the same type of lighting. Also, an office or salesroom may be paying 3 to 4 cents per kwhr for a small power usage, or less than 1 cent for a large usage. The same type of lamp may not be the most economical in each case.

Again, two manufacturers may be making the same type of product with about the same machinery layout, but one may be making a quality-line product in which inspection may be the most important item in the manufacturing process, while the other may be making a price-line product in which low-cost production outweighs quality. These two plants would require vastly different approaches to their lighting problems.

One process may be experimental in nature and considered more or less temporary, while for a similar process the plant may be built for long-term usage. These lighting problems will most likely be different.

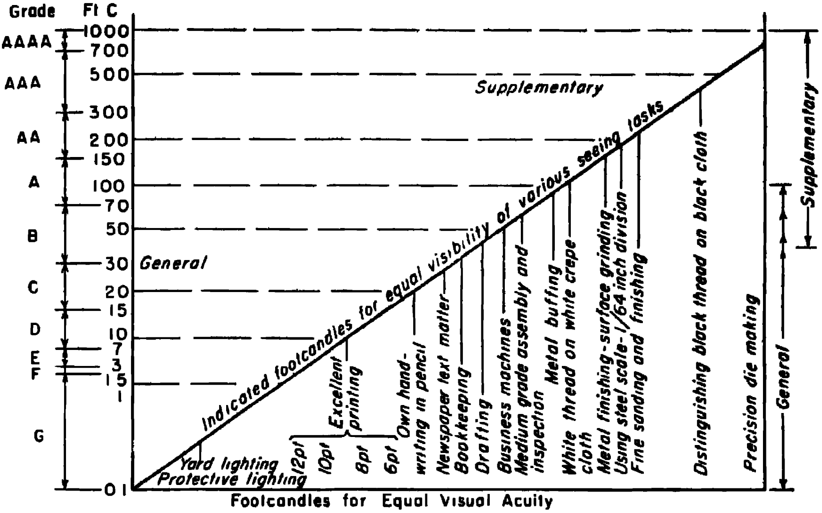

FIG. 13-42. Specifications of general lighting

In an office building, certain areas such as corridors and general conference offices may be adequately lighted with incandescent lamps, while the more detailed work will require lighting levels which can only be produced satisfactorily by fluorescent lamps. The latter are particularly effective in court offices because they help to overcome by psychological means the cramped feeling brought about by the lack of an outside view.

The one requirement which all lighting installations should have in common is that the maintained lighting level and conditions should be adequate for the various industrial seeing tasks.

In general, disregarding somewhat the economics of the problem, the three light sources may have their specific basic applications considered as follows:

1. Incandescent lighting for illumination levels up to 20 or 25 ft-c. For higher levels, wattage requirements and resultant energy costs will be excessive. Also the heat radiated may be a problem.

2. Fluorescent lighting for high illumination levels from 25 ft-c up. Fluorescent lamps illuminate with less glare and less heat and produce many more lumens per watt than do the incandescent lamps. Engineered fluorescent lighting is the most practical form of illumination for precision operations and is particularly effective in inspection departments, machine shops, drafting rooms, and other departments where seeing tasks are most precise.

3. Mercury lighting for high illumination levels where high mountings are involved.

It will prove most satisfactory in foundries, forge shops, steel mills, and large factory areas where the room proportions are excessive. It may be combined with incandescent lamps to bring back the red and orange tones into the over-all lighting spectrum and permit more natural identification of colors such as the worker's skin and production material.

Table 13-22 lists the general industrial applications for various light sources within the limitation of standard present-day light sources. This table shows the overlapping usages of light sources as mentioned above. The grades of illumination noted in Table 13-22 are outlined in Fig. 13-42.

This figure is not necessarily the recommended foot-candle illumination level for the various visual tasks shown. Visual acuity is the ability to see minute detail. Using as a basis 8-point Bodoni Book type (8-point Bodoni Book) illuminated to a level of 10 ft-c and viewed at a distance of 14 in., the other tasks will have the same visibility under the various levels indicated.

In most cases the level of illumination is not critical within 25 to 50 per cent. Actually, there is no substantial difference between 4 and 6 ft-c, 15 or 20, etc. Seeing is a very complicated process, and ease of seeing is, in some cases, more important than visual acuity. The two do not go hand in hand. The final appraisal of a lighting system rests on comfort and see-ability which will be discussed under the main titles How Much Lighting Is Enough for Optimum Seeing? and Illumination Yardsticks. For general purposes it is necessary to refer not to exact levels of illumination but to grades of illumination, as indicated in Fig. 13-42.

Newest Developments in Lighting Sources

A new type of fluorescent lamp called Slimline is approximately ¾ in., 1 in., and 1½ in. outside diameter, 42, 64, 72, and 96 in. nominal length and rated 1,070 to 5,000 lumens. Some of the features of these new lamps are

1. Instantaneous starting; no starter needed
2. Longer life than ordinary fluorescent
3. Higher efficiency; average of 60 lumens per watt
4. Ready adaptation to certain architectural treatments because of its small diameter and longer length
5. Adaptation to flashing

Despite their efficiency, the shape of the present fluorescent lamps prevents their use in ordinary portable units in which a long tube could not easily be accommodated. The lamp manufacturers have developed a circular fluorescent lamp called the "Circline," rated at 32 watts with a 1¼-in.-diam tube and an outside-ring diam of 12 in. This lamp, in addition to being adaptable for use in portable lamps, is being used in industry for inspection lighting.

Other types of light sources may come into use in the near future. Most assuredly, drastic improvements will be made in some of our present systems.

Comparison of Lighting Fixtures and Systems

Lighting Fixtures. An efficient lighting system requires reflectors or luminaires in order to control the light distribution and to reduce the high surface brightness that is produced by the various light sources. For general purposes today, the lighting quality of an installation is frequently judged not so much in terms of lighting intensities or the quantity of light as in the degree of shadow and the amount of direct and reflected glare. The luminaire which controls these factors is the backbone of the lighting system. The type of unit, the desired distribution of light, and fixture suitability for the particular interior depend upon the type of work conducted and the room proportions.

In any given interior or for any type of machine arrangement there may be several methods of illumination design that will produce effective results. With the development of the mercury lamp in 1935 and the fluorescent lamp in 1938, the problem of selecting the types of lighting sources and lighting fixtures for a given design or condition has been greatly multiplied. To ensure that the elements of quantity and quality of lighting will be right, the system of lighting and the type of fixtures should be carefully selected. The choice deserves as much, if not more, consideration as the choice of any of the other tools used in industry.

Except for the standard RLM type of lighting unit, manufacturers have made practically no attempt to standardize fixtures. Their catalogues show thousands of various types and sizes of units, varying from the open-lamp unit to decorative trollers. However, an analysis of the many designs shows that many makes are used to serve a definitely limited number of lighting situations and that practically all the units may be classified and put into a few groups to meet specific installation conditions and seeing tasks.

The different types of reflector and luminaire equipment used currently in the various areas of industrial plants are listed in Table 13-23. This table is an outline of the several classes of fixtures used with the three principal light sources: incandescent, fluorescent, and mercury. After classification, the choice of the particular make may be made, with consideration given to quality, appearance, and ease of installation and maintenance as prime requisites. It must be remembered that the best type and size of lighting unit is the one which meets the need for lighting, contributes the most to aid the worker accomplish his duties, and provides the decorative effect desired. The engineer should not make the choice of lighting fixture or installation on a cost analysis until it is first reduced to a comfort and see-ability basis of comparison. These factors will be discussed later in this subsection.

Ever since the technique of lighting has been a problem for serious consideration, there has been a tendency to use larger surfaces of lower brightness for the distribution of light. Any brightness in close proximity and in the line of vision greater than 1,000 ft-lamberts will tend to be uncomfortable. The best system of lighting confines brightnesses in the usual field of vision to 300 ft-lamberts or less. The general order of brightness of the various light sources and some of the more common types of fixtures are given in Table 13-24. These figures show the necessity for shielding practically all

Table 13-23. Present Types of Lighting Equipment and Systems

Group	Description	Wattage
	Incandescent Industrial	
A	RLM metal-dome reflectors—three sizes. 12 to 20 in. with porcelain enamel reflecting surfaces that provide well-distributed light for simple-factor seeing tasks	Six wattages—150- to 1,500-watt inside-frosted lamps. three wattages—150- to 300-watt white-bowl lamps
B	Glass- or metal-bowl reflectors providing concentration or reflection for more exacting tasks	Six wattages—200- to 1,500-watt; clear or inside-frosted lamps
C	Glassteel diffusers—three sizes combining 10-, 12-, or 16-in. diffusing globes with RLM-type reflector to provide high-quality diffused lighting for more exacting tasks	200- to 1,000-watt clear lamps
D	Deep-bowl high-bay units with specular reflectors to provide lighting in difficult areas where fixtures must be mounted 20 ft or more above floor	Five wattages—300 to 1,500 watts
E	Special dome or trough reflectors with silvered-bowl lamps for diffused lessened-glare lighting conditions	Four wattages—150- to 500-watt silvered-bowl lamps
F	Supplementary units of many sizes, designs, and uses. Available in many types of adjustable mounting. Used only to supplement general lighting	
	Fluorescent Industrial	
G	RLM and open-end units with porcelain-enamel steel reflectors for general lighting in ordinary industrial interiors	Two- or three-lamp 40-watt units. Two-lamp 85 watt units and two- and four-lamp Slimline—120 to 600 ma
H	Continuous troffer for flush mounting. Form of RLM type unit designed for end-to-end mounting; used to provide high level of general illumination in large factory areas or bench lighting. Flush mounting used for installation in acoustical tile or plastic ceilings, particularly in areas where conditions are controlled	Two- or three-lamp 40-watt units. Two-lamp 85-watt units and Slimline
J	Supplementary units of many sizes with diffused or concentrating reflectors. Used in lighting small areas for high lighting levels above 100 ft-c without heat discomfort	
	Mercury Industrial*	
K	RLM standard dome or glassteel units with porcelain-enamel steel reflectors. Used for general lighting in industrial interiors where color and stroboscopic effect are not important	400-watt AH-1 lamp 250-watt CH-5 lamp 100-watt AH-4 lamp
L	Deep-bowl high-bay units with metal, mirrored, or prismatic glass reflectors. Used to provide economical lighting in areas where fixtures must be mounted 20 ft or more above floor	400-watt AH-1 lamp
M	Trough reflector units for high-bay mounting—40 ft or more above floor	3 000-watt H-9 lamp
	Incandescent Commercial	
N	Direct-lighting units with controlled distribution and equipped with louvers or lens plates to reduce the unit brightness. Recessed units give uniform illumination in low ceiling areas and may be used in combination with other units to add variety and achieve unusual lighting effects	Four wattages—100 to 500 watts

Table 13-23. Present Types of Lighting Equipment and Systems (*Cont.*)

Group	Description	Wattage
P	Semidirect or semi-indirect units including a variety of luminous-bowl or prismatic-glass fixtures. Used to provide illumination fairly well distributed on both horizontal and vertical work surfaces. In using this unit it is necessary to guard against brightness in the field of view whenever prolonged visual tasks are encountered	Five wattages—200 to 1,000 watts
Q	Indirect lighting units with metal, glass, or plastic bowls which direct most or all the light to the ceiling for reflection to the working plane. This type of unit is inherently inefficient but has the advantages of low brightness, inconspicuous appearance, and almost shadowless, uniform distribution of light. Very uneconomical for lighting levels above 30 ft-c	Four wattages—300- to 1,000-watt inside-frosted lamps
	Fluorescent Commercial*	
R	Suspension-type semidirect or semi-indirect units with glass and plastic diffusing panels or metal louvers to reduce brightness and shield the lamps from the eye. May be used singly or continuously for high ceiling areas. Distribution of different units varies, but the majority of fixtures light both up and down	Two to four lamps. 40 and 85 watts, and two- or four-lamp Slimline—120 to 600 ma
S	Surface-mounted units similar to group R except that they are designed for mounting directly on the ceiling. For general lighting in all rooms with low ceilings (approximately 10 ft or less) or in any room where the width is equal to or greater than the ceiling height	Two to four lamps. 40 and 85 watts and Slimline
T	Recessed troffer units for installation flush with the ceiling surface and equipped with louvers or glass diffusing or lens panels; designed for use with acoustic-tile ceilings or simple installation in lines or rectangular forms in any suspended ceiling. Fixture appears to be part of ceiling and is only type of direct lighting unit satisfactory for office use	One and two lamps. 40 and 85 watts and Slimline
U	Indirect lighting units with metal or translucent glass or plastic bowls which direct most of the light to the ceiling for reflection to the working plane	Two and more lamps. 40 and 85 watts and Slimline
V	Suspension-type direct unit with metal or low-transmission-factor glass. Similar to group R and has characteristics of group Q except that this unit may be used to produce lighting levels up to 100 ft-c economically	Two and three lamps. 40 and 85 watts and Slimline

* There are many combinations of incandescent and mercury industrial systems. The most popular is an alternate spacing of incandescent and mercury luminaires. Other units are combination reflectors, either metal or glass, with one mercury lamp and one or more incandescent lamps.

lamps in an industrial system designed for maximum comfort and see-ability except when the fixtures are mounted high and outside the normal viewing angle. Table 13-24 also shows that, with reference to brightness, frosted incandescent bulbs are superior to clear ones for general lighting. They reduce the shadows cast by small objects because the entire surface of the frosted bulb acts as a light source. The larger the light source is in relation to the obstruction, the smaller and less pronounced will be the shadows.

Figure 13-43 is a chart which indicates the approximate wattage load per square foot required to produce different light-intensity levels with the various types of lighting fixtures listed in Table 13-23. On the chart, follow the horizontal line beginning at the maintained foot-candle value desired, until it intersects the curve corresponding to the fixture type. The watts per square foot may be read directly below the intersection point. For large rooms (50 by 100 ft) higher horizontal intensity levels may be expected; for small rooms (12 by 15 ft) lower values will result. This chart should be used for estimating loads to determine the order of magnitude only. The quantity and quality of lighting that will be obtained in a working area under normal working conditions will depend upon such important items as brightness, color, contrast, room proportions, and the size and shape of the objects in the room.

Table 13-24. General Order of Brightness of Various Light Sources and Luminaire Equipment

Light source or equipment	*Exposed brightness approx ft-lamberts*
1. Incandescent lamps	
a. Open dome and bowl reflectors	
Clear bulb—filament	3,000,000
Inside-frosted bulb—1 000-watt lamp	120 000
Inside-frosted bulb—500-watt lamp	95,000
Inside-frosted bulb—200-watt lamp	65 000
Inside-frosted bulb—100-watt lamp	50,000
Inside-frosted bulb—60-watt lamp	16,000
b. RLM domes and white	
Bowl lamps—300-watt lamp	10,400
Bowl lamps white—200-watt lamp	6,300
Bowl lamps white—150-watt lamp	9,500
c. Glassteel diffusers	
16-in. globe—1 000-watt lamp	6,300
16-in globe—750-watt lamp	4,800
12-in globe—500-watt lamp	5,400
12-in. globe—300-watt lamp	3,100
10-in globe—200-watt lamp	2,850
d Open dome and trough reflectors (mat finished with silvered-bowl lamps)	
26-in diam side of reflector—500-watt lamp	1,820
19-in diam side of reflector—300-watt lamp	2,400
19-in diam side of reflector—200-watt lamp	1 720
2 Type-H mercury lamps	
a. Open dome and bowl	
400-watt type-H-1 lamp	407 000
250-watt type-H-9 lamp	390 000
b Glassteel diffusers—16-in globe	
400-watt H-1 plus three 150-watt incandescent	7 200
400-watt H-1 lamp	5 000
3. Fluorescent lamps	
a. Open enameled-trough reflectors	
85-watt 3500° white 60-in T-bulb	2 180
40-watt 3500° white 48-in T-bulb	1 750
40-watt 4500° white 60-in T bulb	950
b. Lenses and louvers when properly applied will reduce the surface brightness to 300 ft-lamberts and less	
4. Natural brightness	
a. Sun at zenith.	450,000 000
b. Cloudless sky	2,500–5 000
c. Moon (full)	900–1,300

Lighting calculations and tables giving light-intensity levels for continuous-row 40-watt fluorescent lighting units may be used for the 425-ma Slimline lighting units as their lumen-output value per foot of lamp is approximately equal.

The most important facts concerning the selection of lighting fixtures are listed below:

1. The luminaire is the backbone of any lighting system, for upon it combined with the light source depends the quantity and quality of the illumination.

2. The lighting installation in both commercial and industrial plant areas should be made as inconspicuous as possible.

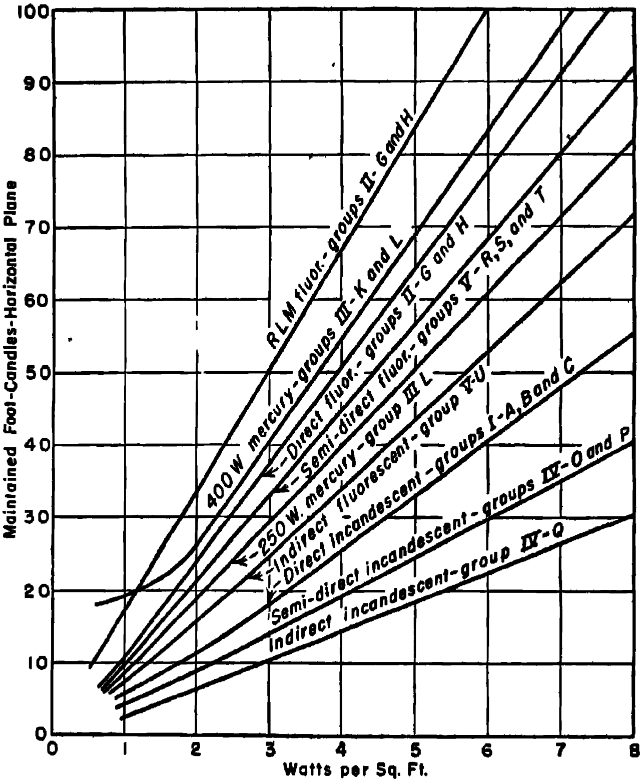
3. Lighting fixtures should be carefully designed with proper shielding and made of materials to provide high efficiency and ease of maintenance

4. In planning a lighting system for any project, the lighting result should first be selected. The subject of "lighting result" is very broad in scope and covers

a. The aesthetic effect, architectural treatment, and decorative scheme
b. The type, size, and color of the light source
c. The type of luminaires, reflectors, or lighting equipment
d. The wiring method to be used

5. The incandescent lamp is a highly concentrated light source, and when used for general lighting, even in indirect equipment under the most favorable lighting conditions, the contrasts in brightness are usually so great that lighting levels in excess of 30 or 35 ft-c are seldom comfortable.

6. The fluorescent lamp is a diffuse light source and has a low surface brightness. In the standard lamps the order of brightness is about four candlepower per square inch, and while this is too great for comfort when used unshielded, it is quite simple to reduce the brightness to safe limits by simple luminaire construction.



This chart is intended as a guide in estimating load and wiring capacities for foot-candle levels with various types of lighting fixtures. When planning layouts for selected fixture, the illumination should be calculated using photometric distribution curves for that particular figure.

Fig. 13-43. Approximate load required to produce different light-intensity levels with various types of lighting fixtures.[8]

7. By properly combining several fluorescent lamps within a reflector or behind diffusing panels, it is easy to create an extended low brightness source. For this reason, direct-type fluorescent-lighting units can be made to produce just as effective lighting characteristics as an indirect incandescent-lighting installation.

8. When heating from the artificial lighting source is a problem, the fluorescent lamp actually directs less radiant heat toward the worker than does an incandescent lamp of the same wattage.

9. Loss of human life, as well as property by explosions and fires, warrants careful study where the application is to be made for hazardous chemicals, processes, and

industries. The increased expense incident to vaportight, dust-tight, and explosion-resisting equipment installations is justified for hazardous locations.

Lighting Systems. In general, there are three types of lighting systems: direct, semidirect, and indirect. Listed below are the advantages and disadvantages of each system.

The general advantages of the *direct* type of illumination are

1. First cost is lowest.
2. Efficiency of power utilization is best.
3. Maintenance upkeep is lowest.

The disadvantages are that it is

1. Not so good as other systems as far as direct and reflected glare is concerned.
2. Worse for the production of shadows but, with proper equipment and proper installation, may be made satisfactory.
3. Not so favorable in appearance as other types. The direct type of illumination is applicable for most industrial installations, but for eye comfort such installations must have louvers, reflectors with proper light cutoff, or diffusing glass plates and panels.

The advantages of *semidirect* are

1. Favorable appearance
2. Good for elimination of shadows and glare
3. First cost intermediate between the other two types
4. Second in efficiency as far as power and maintenance are concerned

The disadvantages are that it is

1. Not so good as indirect lighting so far as direct reflected glare is concerned
2. Not so efficient for use with dark ceilings and walls

The advantages of *indirect* are that it is

1. Best for the elimination of glare
2. Best for the elimination of shadows

The disadvantages are

1. Poor efficiency as far as power and maintenance are concerned
2. Highest first cost
3. Cannot be economically used with dark ceilings and walls

In making a selection of lighting fixtures, various factors must be considered with respect to the particular problem at hand. For instance, in an office the major factors rank as follows:

1. Freedom from direct and reflected glare
2. Adequate illumination levels on the horizontal working plane
3. Pleasing aesthetic or decorative results
4. Utilization factors, such as economics of installation and maintenance

In general industrial-process areas the order of importance might be

1. Adequate illumination levels on both horizontal and vertical working planes
2. Freedom from detrimental direct and reflected glare
3. Utilization factors
4. Aesthetic or decorative results

Many needs for lighting around a plant, such as stairs, storage areas, loading platforms, and like areas, are well satisfied by the simplest and cheapest expedient. Comfort and see-ability, as far as a lighting quality is concerned, will be discussed under Illumination Yardsticks. Installation hazards, such as explosion-resisting, excessive corrosive conditions and dust, call for different forms of fixture construction and location, all of which reduce the lighting output which must be charged against safety and/or ease of maintenance. Even clear-glass covers reduce the light output of fixtures 10 to 20 per cent.

Chemical-process plants in almost all cases have a particularly difficult problem of lighting. The dangerous nature of many of the chemicals requires dust-tight and explosion-resisting lighting fixtures. Also, there is a need for special lamps and equipment for applications: (1) where high ambient temperatures prevail, (2) where there is excessive vibration, and (3) where the service is too rough for the standard lamps.

In general, there are three main methods of lighting for explosive or highly flammable atmospheres, and the choice of the method depends upon the seriousness of the risk involved.

1. Light sources placed external to the building and arranged to throw their light through a glass roof or window direct on the working plane or by reflection from light-covered surfaces

2. Light sources placed outside the danger zone but inside the building or in the walls so that relamping can be done in a nonhazardous location

3. Flameproof fittings or lighting units under a small inert-gas pressure employed for those hazardous gas areas where it is impractical to light the working area from sources listed in (1) or (2).

In most explosive-dust locations it is sufficient to use a well-gasketed dust-type of fitting which effectively encloses the lamp, has a smooth contour which prevents an excessive accumulation of dust, and which is designed to hold the temperature of the unit within safe limits.

In addition to installations in chemical plants which require treatment for explosive materials, fumes, and vapor, there are other areas which require vaporproof units for installation in areas where excessive moisture, alkali fumes and vapors, and acid fumes and vapor are prevalent. Fittings or hoods for use with vaporproof units are made of black or galvanized cast iron, silicon aluminum alloy, or bronze. In general, in locations where explosive materials, acid fumes, or excessive moisture are present, either the cast iron with an asphaltum-base-paint finish or the silicon-aluminum-alloy fitting will give good service. In places where alkali vapors are present, galvanized cast-iron fittings are preferable; aluminum fittings should not be used. In some extreme acid conditions, lead-alloy or plastic fittings should be considered.

Some of the significant facts concerning the selection of a lighting system for use in various plant areas are as follows:

1 The best type of natural lighting is that which is reflected from a cloudless northern sky. It is uniform and diffused and produces no highlights, glare, or shadows.

2. The closest approach to natural light obtainable with artificial lighting is by means of a large-area low-brightness light source. Properly applied indirect lighting approaches the natural condition noted in 1 if the lighting level is adequate for the work involved. However, the broad expanse of the illuminated ceiling is by far the brightest area in the room. Glare may not be eliminated to the point where it is not objectionable.

3. All local lights for a machine should be built in and made just as much a part of the machine as any of its working parts. Very few local lights will prove satisfactory when they are under the unguided control of the operator.

4. With incandescent lamps, indirect-type lighting is usually considered essential for satisfactory office and drafting-room lighting. The lower brightness of the fluorescent lamp permits the use of semi-indirect equipment to give similar lighting quality, with the result that an increase of lighting efficiency of about one-third is gained because of the differences in the utilization factors of the semi-indirect equipment over those of the direct type.

5. The fluorescent lamp has little competition in any industrial application so far as brightness, which may cause uncomfortable direct or reflected glare, is concerned. It is easier to achieve all the objectives of adequate lighting with a fluorescent-lighting system than by any other means.

6. The larger the light source, in relation to an obstruction, the better. Shadows will be smaller and much less pronounced.

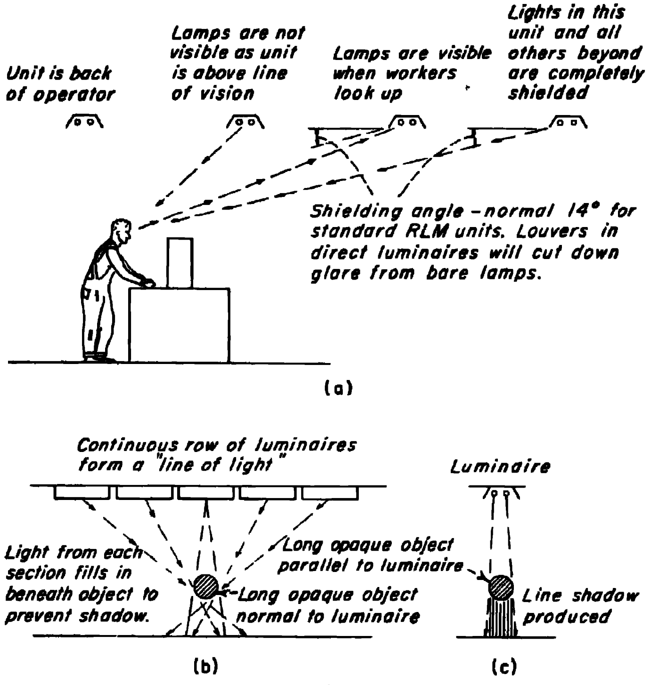
7. Often the fluorescent lamp has been referred to as a large-area low-brightness source. This claim is not entirely true, since the lamp itself is a slender linear source whose width is very small in comparison with its length. However, with reference to brightness and glare, fluorescent equipment can be designed, fabricated, and engineered for installations which make it an excellent low-brightness source.

Exterior Plant Lighting. Exterior plant lighting is used in industrial plants for (1) protection; (2) passageway, roadway, and yard illumination; (3) outdoor work; (4) advertising, stack lighting, etc.

Protective-lighting installations must be completely reliable and resistant to weather, damage, and sabotage. A failure of a part of the system should not leave a vulnerable area unprotected.

Most exterior plant lighting is done by some form of street-lighting unit or floodlighting equipment. The following classes of equipment are available:

1. Street-lighting units with distribution controlled by reflectors and lenses mounted on poles for lighting fence lines, roadways, wide passageways between buildings, etc. A Fresnel-lens unit developed specifically for fence lighting provides a uniform level of illumination with good utilization in a vertical plane—a most important feature in protective lighting.



Unit is back of operator
Lamps are not visible as unit is above line of vision
Lamps are visible when workers look up
Lights in this unit and all others beyond are completely shielded
Shielding angle - normal 14° for standard RLM units. Louvers in direct luminaires will cut down glare from bare lamps.
(a)
Continuous row of luminaires form a "line of light"
Light from each section fills in beneath object to prevent shadow.
Long opaque object parallel to luminaire
Long opaque object normal to luminaire
Luminaire
Line shadow produced
(b)
(c)

FIG. 13-44. Fluorescent light techniques (a) Luminaires placed normal to the line of sight provide maximum shielding of lamps. (b) Luminaires run perpendicular to long opaque objects tend to eliminate shadows. (c) Luminaires run over and parallel to objects tend to create sharp line shadows.

2. Floodlight projectors, either open or closed units, for general illumination of large areas, for high levels around gatehouses, for particularly vulnerable positions, and for high-mounting long-distance projection.

3. Searchlights, high candlepower, narrow beam, with pilot-house controls mounted on sentry boxes and guard towers.

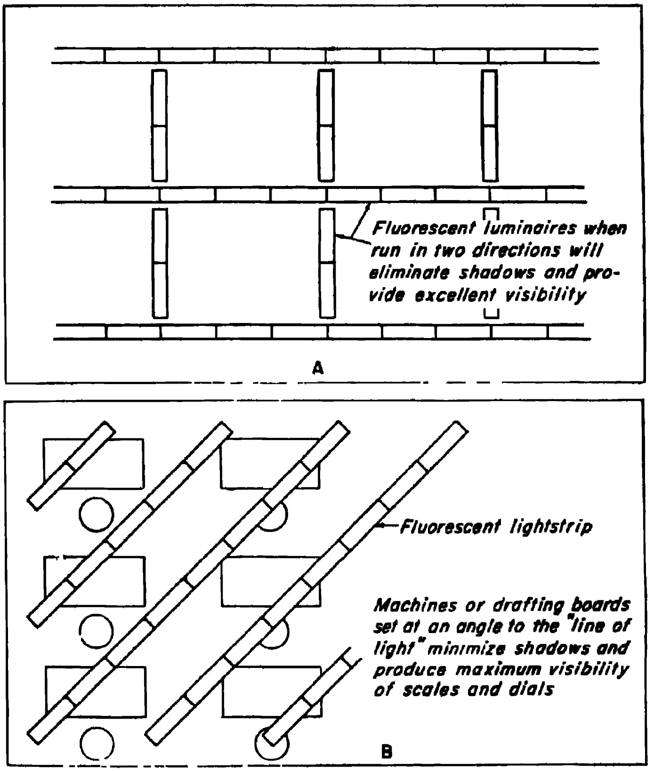
4. Symmetrical or elliptical angle reflectors or reflector lamps with flood or spot distribution for sign lighting, gates, doors, control stations, or other small areas.

The design of the exterior plant lighting arrangement is dependent upon the character of the installation to be illuminated. For close-up illumination, it is immaterial whether or not broad-beam floodlights or street lights are used. However, experience indicates that street lighting is usually more economical and efficient for general outdoor illumination than are the other types of installation. A row of modern 6,000-lumen enclosed street lights, spaced at approximately 125 ft and mounted at a height of about 23 to 25 ft will provide an illumination averaging 0.2 to

0.3 ft-c. in a strip between 60 and 100 ft wide. Reasonable estimating costs of street-lighting installations are $100 per 100 ft where poles have to be supplied or $60 per 100 ft where the units and aerial wiring may be mounted on existing poles.

Future Developments in Lighting Installations

Industrial plants present an infinite variety of processes, machinery layout, and materials to be handled, but these all combine with some modifications the same application of illumination to machines, bench work, inspection, office areas, etc. Each individual problem must be studied to determine the proper type of lighting system to be installed. To prove satisfactory, the system must be engineered on the basis of certain fundamentals, such as the purpose for which the lighting is needed, the physical characteristics of the area to be lighted, the illumination intensity necessary, and the expected results to be attained.



Fluorescent luminaires when run in two directions will eliminate shadows and provide excellent visibility
A
Fluorescent lightstrip
Machines or drafting boards set at an angle to the "line of light" minimize shadows and produce maximum visibility of scales and dials
B

Fig. 13-45. Two methods of installing continuous-row luminaires to produce maximum visibility results.

The days are past when any symmetrical pattern of outlet spacing would do and fixtures were chosen after construction was under way. The present trend is toward built-in lighting and functional lighting treatment from large-area low-brightness light sources by properly combining several lamps within a reflector or behind diffusing glass or other shielding material. Line of light, using fluorescent continuous-strip luminaires, will be most useful in developing lighting systems. The advantages of this system are illustrated in Figs. 13-44 and 13-45.

Figure 13-44*A* shows that, when fluorescent lighting strips are run at right angles to the normal line of sight, maximum shielding will be produced

Figures 13-44*B* and 44*C* show the necessity of locating the lines of light with reference to the machines and work in order to prevent harsh shadows.

Figure 13-45 shows two methods of installing continuous-strip luminaires to produce maximum visibility results.

Figure 13-45*A* shows a system with the luminaires strip running in two directions to form a grid system of lighting. This type of system, when properly located with reference to the machines and work, will almost entirely eliminate shadows.

When direct-type lighting is used in offices or drafting rooms, the fixtures should be equipped with louvers or lens plates to improve shielding. Figure 13-44*B* shows a scheme where the machines or drafting boards are set at an angle to the lines of light. This system will minimize shadows and produce maximum visibility of scales and dials.

There will be new lighting developments in the future. There is every indication that the present light sources and luminaire designs offer great opportunities for sound and constructive planning in the field of illumination. There will be little danger of obsolescence provided the intensity level is adequate for the fundamentals discussed under Illumination Yardsticks and provided these fundamentals are not ignored in planning the installation.

Combined light and power systems, using higher voltage lighting circuits, supplied from load-center distribution systems will provide a less expensive over-all electrical system for some types of industrial plants.

For incandescent lamps, 120-volt systems have been used almost universally. Higher voltage incandescent lamps are fragile and are generally not satisfactory. All fluorescent lamps have ballast in series with them. By combining a slight transformer action with the ballast, the fluorescent lamp can be operated on circuits from 120 to 265 volts. Standardized ballast ratings are 118, 208, 230, and 265 volts. For general lighting, the introduction of higher voltage fluorescent-lamp ballast has opened new avenues to higher voltage lighting circuits, thereby reducing the cost of the system which supplies the lighting load. The 460/265-volt three-phase four-wire grounded-neutral system can supply not only the 460-volt power but also the 265-volt power for general area fluorescent-lighting circuits. Fluorescent-lamp and starter voltages are essentially the same regardless of the voltage rating of the ballast. It is therefore believed that no sacrifice in safety is made with the higher voltage circuit operation, since in changing ballasts the circuit should be deenergized regardless of circuit voltage. Voltages as high as 260 should be used only in fixtures for general factory lighting where the mounting height is more than 8 ft. The National Electrical Code requires that all lighting for offices, individual local units for benches, machines, etc., shall be operated at a maximum nominal rating of 120 volts.

Amount of Light for Optimum Seeing

The main problem of illumination engineering has to do with long hours of close attention to more or less severe seeing tasks in the plant, shops, offices, and drafting rooms. Lighting intensity is only one factor to consider in the matter of good lighting practice. However, in a large majority of cases, improved seeing demands higher levels of illuminations for the visual tasks involved. Speed of vision is directly proportional to the ability to see detail. Light acts as a magnifier of detail. The eyes are thus greatly handicapped when they have an inadequate amount of light for ease of seeing, but the level required to produce maximum possible visual acuity—the ability to discriminate fine detail—is not usually required. This is especially so when the job to be done does not demand great visual effort. It may probably be quite unrelated to the actual seeing of detail. On the other hand, the fact that lighting of a given intensity is sufficient to enable a given task to be performed does not necessarily mean it c[illegible] be done easily. It is not correct to limit the considerations to mere momentary adequacy. When a job can be seen clearly, easily, and comfortably over the entire working period, then, and then only, can it really be done well.

It is not so much what your eyesight is, but what it can do, that counts. A century or so ago, when most work was done outdoors, a "normal" eyesight meant good vision at a distance. Today, much of the working world is under our noses, and normal eyes do not exist. Some work requires clear vision 8 in. from the face and other jobs demand extreme depth perception, color sensitivity, or lightning rapidity in far-to-near accommodation.

When someone asks "How much lighting is enough?" a flood of questions demand answers:

1. What are the ages, eye characteristics, and previous light education of those who work by the illumination?
2. What kind of work is involved? What is its size, color, background, etc?
3. Is the visual task a prolonged one?
4. What kind of performance is demanded? Are speed and accuracy vital factors?
5. Is the work to be viewed in a horizontal, vertical, or sloping plane?
6. What is the clarity of the atmosphere?
7. Are industrial hazards present, and what is their nature?
8. What humanitarian aspects of seeing, such as eyesight conservation and fatigue, shall be considered?
9. Are aesthetic or artistic effects, having to do with decorative functions, to be a governing consideration in the selection of the system?

Many installations supplying 50 to 100 ft-c are now in use with supplementary illumination of from 150 to 250 ft-c. However, a superabundance of light does not answer the purpose. It often adds to the difficulty of concentration. Lighting has suffered from the foot-candle concept or method of measuring the illumination level. Light output is measured in lumens, and the value of the illumination is merely the arrival of some of these lumens at some surface. The greatest value of light output for the least wattage is certain to result in objectionable features, such as excessive shadows and reflected glare. Many factors determine the adequacy of the installation.

Vision involves four fundamental elements:

1. The *task* of what one sees (not controllable)
2. The *eyes* with which one sees (indirectly controllable)
3. The *light* which makes it possible for the eyes to function (controllable)
4. The *surroundings* or the background against which the task or object is viewed (controllable to a degree)

Each of these is influenced by many other items. Providing light for seeing becomes a problem of controlling and coordinating the various factors outlined below:

1. Visibility requirements as determined by the character of visual task and the operation involved are
    - *a.* Size of the object to be seen
    - *b.* Time allowed for seeing
    - *c.* Contrasts in reflection factors
    - *d.* Average reflector factor
    - *e.* Color differences
2. Ability to see is influenced by the following external conditions:
    - *a.* Average brightness of surroundings
    - *b.* Size, brightness, and location of bright areas within the field of view
    - *c.* Brightness contrasts within the central field of view
    - *d.* Brightness within the surrounding field
    - *e.* Preexposure of the eye to brighter or darker surroundings

These modifying factors, which will be discussed under Illumination Yardsticks, are much more important in influencing the over-all appraisal of a lighting system than the absolute value of the illumination level. This is the reason why grades of illumination are referred to in Table 13-22 and Fig. 13-42. As noted before, there is substantially no difference in most cases between 4 and 6 ft-c, 10 and 15 ft-c, 20 and 30 ft-c, or 50 and 70 ft-c, etc. Brightness relationships, rather than high lighting intensities, determine good seeing conditions. For this reason it is necessary to study the various visual tasks and their background relationship for proper lighting results. In most industrial plants, the assortment of machines varies; the operations, designs, or processes change; and differences exist in tolerances and degree of inspection. Therefore, the lighting factors involved, even for industries in like process groups, do not always remain the same. Furthermore, a complete lighting system that will prove entirely satisfactory cannot be supplied on a blueprint unless the designer has an intimate knowledge of the processes and their operational requirements.

As a basis for selecting the lighting intensity, the most trustworthy information about minimum required recommendations is contained in lists approved by the American Standards Association. These lists give values of minimum foot-candles in service measured on a horizontal plane 30 in. above the floor.

Thus all that seems necessary is to spot a sufficient number of outlets on the plans and specify light sources large enough to produce the intensity recommended. The problem isn't so easy. There are many items encountered in most industrial processes which will lead to unsatisfactory lighting results unless they are given proper consideration. The most important are

1. A large percentage of the work or surfaces to be seen in industrial plants, such as gauges, verniers on machines, etc., are vertical or inclined, rather than horizontal.
2. In a room full of equipment and material, the light from a general lighting system is very likely to be blocked by interference and sponged up by the "surround," expiring without reaching the critical work surfaces.
3. Lighting requirements for industrial plants are different for each type of plant even though the same natural laws and engineering principles are effective.

A ray of light falling straight downward on a vertical surface produces no light on that surface. Increasing levels are obtained as the slope of the ray increases up to 35 deg from the vertical. As the ray slopes still more, the amount of vertical illumination drops because of the shrinking effect of increasing distance. With most artificial lighting systems, the lighting level on a vertical plane is seldom greater than one-half that produced on a horizontal plane at the same location. In the majority of cases it is much less. As the manufacturing art advances, machinery becomes more complex, and workmen must react more quickly to every change that occurs in their work or their environment. Progressively better lighting is required with every advance in the technique or speed of production.

When a person enters or when a machine is brought into a room, the illumination falls immediately. The degree of this decrease depends on the size, shape, and color of the objects in the room. In one recent machine-shop installation the illumination measured in an empty room was 45 ft-c, but when the machines were installed the illumination dropped to 33. When illumination on vertical surfaces is important, special consideration should be given to the fixture locations, and luminaires should be chosen that will give distinctly higher candlepower in directions nearer the horizontal than the vertical axis.

A symmetrical system of general lighting for industrial areas is very likely to be full of obstacles and to produce unsatisfactory lighting results. In a large empty room or one where the machines are low in relation to the work positions, many lighting units can contribute to the work. When machines that block the light are installed, only a few luminaires produce light that reaches the work. A recent check of a drafting-room installation which was advertised as a 50-ft-c job showed that the useful illumination on the vertical-type drafting boards, inclined to a very steep fixed angle, was less than 15 ft-c. The "in-service" lighting level will be much lower than the calculated value unless it is especially designed to suit the work position, with proper consideration given to fixture location and luminaire selection, so that the light liable to interference is controlled.

The worker's eyes do not see foot-candles unless they are looking directly at the light source. Reflected light, and not incident light, is what reaches the eyes and causes objects to be visible. Reflected light is measured in terms of brightness, the unit for which is the foot-lambert.

The illumination necessary to reveal an object is subject to more or less accurate determination, provided the following conditions can be correctly stated:

1. Size of detail
2. Distance from eye
3. Difference in reflection factor between the detail and its immediate surroundings

Figure 13-46 is a nomograph of the illumination required at the viewing angle for a seeing task when the above conditions are known. For example, a detail 8/1,000 in. in size, when viewed at a distance of 15 in., will subtend an angle of 1.83 ft (log: visual angle = 0.26). With a difference in reflection factors of 0.4, the illumination required will be approximately 21 ft-c.

Again, most problems cannot be solved so easily. Size of the detail to be seen and the difference of reflection factors may present quite a problem. For example, in the simple process of threading a needle, one does not only have to see the eye of the needle and the thread, but one must see when the thread is nearly in the center of the eye. This problem, like many other cases in industry, may present a more difficult task than the original one.

Up to the present the most serious handicap that the technical man has been under is the fact that there is no universally agreed-upon method of assessing the difficulty of a seeing task or of estimating how tired the performance of a task has made the person performing it.

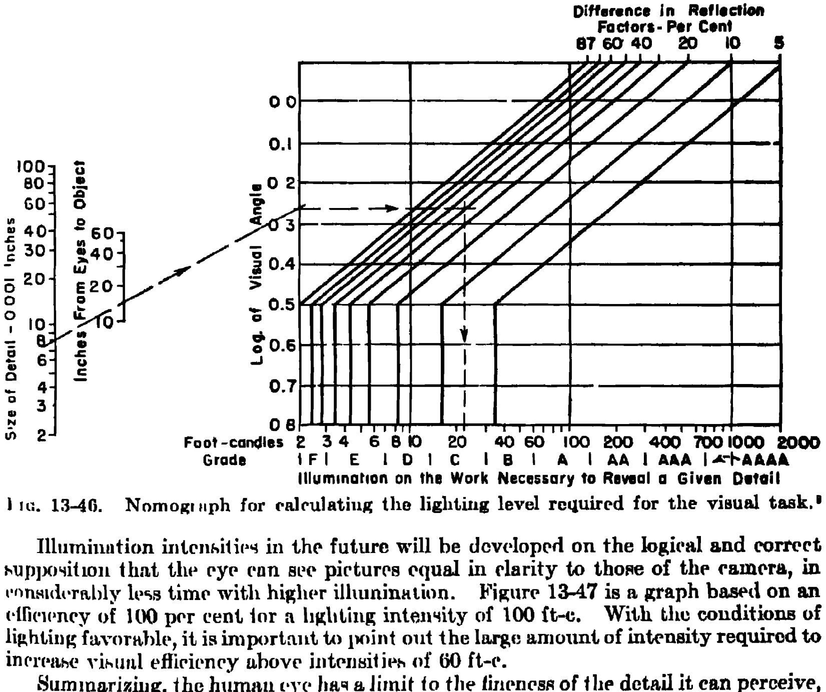


FIG. 13-46. Nomograph for calculating the lighting level required for the visual task.[9]

Illumination intensities in the future will be developed on the logical and correct supposition that the eye can see pictures equal in clarity to those of the camera, in considerably less time with higher illumination. Figure 13-47 is a graph based on an efficiency of 100 per cent for a lighting intensity of 100 ft-c. With the conditions of lighting favorable, it is important to point out the large amount of intensity required to increase visual efficiency above intensities of 60 ft-c.

Summarizing, the human eye has a limit to the fineness of the detail it can perceive, and it is impossible to go below that limit without optical aids to vision. To approach the limit requires an illumination of 50 to 60 ft-c under ideal seeing conditions, and many tasks can be made substantially easier by intensities up to 1,000 ft-c.

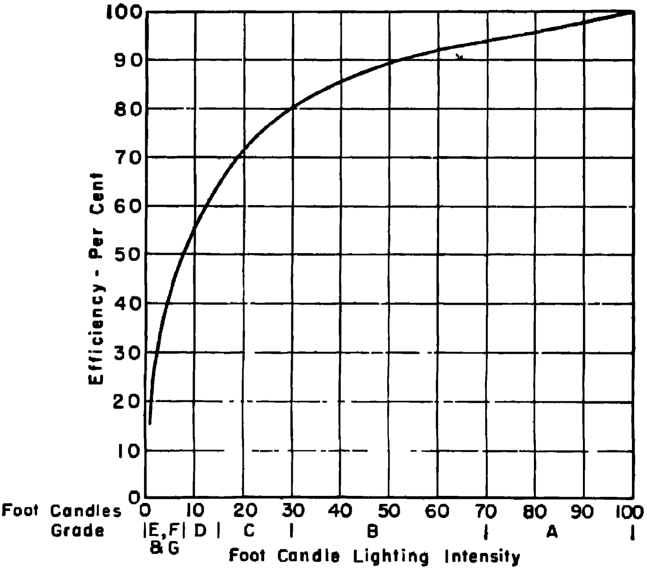
The most important facts concerning the level of lighting intensities are listed below:

1. From a study of the color-response characteristics of the human retina it might be concluded that the yellow color, such as produced by the sodium-vapor lamp which has all of its luminous output concentrated at the 5890 Å wavelength, would be the best for general-purpose lighting. A study of this and other monochromatic lamps shows that they do not meet the broad criteria of satisfactory interior illumination.

Man's seeing judgment depends to a large extent upon the color of the object being viewed. Monochromatic light greatly distorts colors, and any effect in favor of such light may be completely counterbalanced by the deleterious psychological effects upon individuals especially the effects of those colors which change the appearance of the skin.

2. The eye automatically and unconsciously adapts the size of the pupil to the brightness of the field of view; the aperture increases with a decrease in field brightness and decreases with an increase in field brightness.

3. A significant factor in most efficient lighting is the time available for seeing. The workmen's eyes, like a camera, can take "snapshots" when the illumination is high, while with insufficient light it must take "time exposures." Thus, where workmen must react quickly to changes that occur in their work or environment, progressively better lighting is required for every advance in the technique or speed of production.



This chart shows the relative efficiency of an average human eye based on its ability to perceive under various levels of illumination under the best type of lighting. (Uniform and diffused with no shadows, no high lights, no glare and no reflection such as that reflected from a cloudless northern sky).

Fig. 13-47. Lighting intensity vs. visual efficiency.

4. Both speed of vision and visual acuity increase sharply (Fig. 13-47) up to 50 t 60 ft-c, while both increase at a lower rate of light intensities above 60 ft-c. Some gain is realized in higher levels of lighting, probably up to 1,250 ft-c, provided the surroundings are adequately illuminated. The gain for better lighting is greater for people who have eye defects. A decline of visual efficiency below 20/40 approache serious proportions.

5. High intensities of artificial illumination, particularly incandescent lighting, have so much invisible heat energy associated with them that cooling systems becom necessary.

6. Varying brightness contrasts are a much more effective factor in seeing than in increasing the intensity of the illumination proportionally upward.

7. Unless the worker is looking directly at the light source, his eyes do not see foot-candles (incident light) but foot-lamberts (reflected light). Objects are seen by light reflected from them, and in some cases, a very high average foot-candle level

actually reduces the ability to see his work. Because of reflection-factor differences, the brightness of the surroundings may be greater than the brightness of the work.

8. The average flux method commonly used in calculating depreciated illumination is

$$\text{Ft-c} = \frac{\text{total lumens} \times \text{utilization factor} \times \text{depreciation factor}}{\text{floor area}},$$

It cannot be successfully used in a large percentage of industrial applications. It may be used as a basis for calculating the average lighting level on a horizontal plane throughout the entire area, but it tells nothing of the difference in lighting levels between various locations or how much light is actually delivered to the work position, particularly where it is inclined, vertical, or underneath a projection of the machine or workpiece. It is necessary to go much further than providing mere illumination; study of what is being illuminated and the method to be employed must be coordinated with the straightforward engineering problem of illumination.

9. The only real test of a lighting installation is by working at the job for which it was designed. Quality of lighting is often equal in importance to quantity of lighting.

10. One of the most salient facts concerning the relationship of light to sight is the change the human eye undergoes during its life. The pupil of the human eye contracts with age, reducing the amount of light that reaches the retina. This is not a disease but is a condition incident to age. There are general physical changes throughout the whole body between the ages of 40 and 50. The result is a lowering of the muscular tone with the eyes showing a slight blurring of near vision. No special treatment or use of glasses for close work is necessary. However, in order to counterbalance this condition and to maintain the same brightness of the retinal image, the level of illumination should be increased about 25 to 50 per cent.

11. Ordinary clear crown glass used in eyeglasses and safety goggles absorbs at least 10 per cent of the reflected light. Their use will, accordingly, require corresponding increases in lighting intensities.

12. The Illumination Engineering Society Lighting Handbook, published in 1947, recommends 5 ft-c minimum for very easy seeing tasks, 10 ft-c for casual seeing tasks, 30 for ordinary and 50 for difficult seeing tasks. Very difficult tasks may require up to several hundred foot-candles.

Illumination Yardstick—Complaints and Factors That Affect Lighting Results

The purpose of the following material is to discuss artificial-lighting conditions in connection with seeing that will help the eyes as much as possible in the performance of their allotted tasks. Any specification of the most desirable conditions must be related to ideal requirements. The fact that some of the conditions so specified may be impracticable or economically impossible for certain types of installations does not alter the fact that they are desirable. Almost always the ideal that is talked about today is made technically possible only tomorrow.

There is no perfect lighting system: every type, even natural daylight, possesses some fault.

With respect to artificial lighting, the most important factors in determining the lighting results are *comfort* and *see-ability*. Installations that become obsolete quickly are principally those in which the lighting is uncomfortable and/or inadequate for the job. Uncomfortable lighting causes much greater eyestrain and fatigue than an insufficient light-intensity level. The factors that tend to make a lighting installation comfortable are not engineering and physics alone but a branch of applied psychology. It is comparatively easy to design a lighting installation for efficiency, somewhat more difficult to design an installation for aesthetic effect which will please a given group of workers, and very difficult to design any type of installation which a given group will at once consider *comfortable*.

The reason for this is that comfort depends upon personal preferences which are influenced, to a large degree, by habit and previous experiences. Lighting is for people to see by. All humans do not react alike under fixed conditions, nor do they have the same likes and dislikes. Comfort is, therefore, a subjective affair and is not predictable; however, for the purposes of this discussion, it will be defined as freedom from any objectionable sensations and painful, disagreeable, or irritating conditions.

What are these conditions that are uncomfortable and objectionable in the over-all results obtained in a lighting system? The principal causes of inadequate lighting and their relation to physical reactions are given in Fig. 13-48. As a reminder that seeing is an activity of the entire human being, it has been estimated that one-quarter of our bodily energy is used in seeing. When adequate lighting levels are available for the seeing task, other factors upon which visibility and ease of seeing depend are too commonly neglected to make the most of the light that is available. Where the illumination level is adequate, the distribution of light becomes the most important feature for comfortable and efficient visual conditions.

Fig. 13-48. Common causes of inadequate lighting and their relation to physical reactions.

Table 13-25 lists the common causes of unsatisfactory lighting and suggests remedies for correcting these conditions. In suggesting remedies or specifying adequate lighting conditions, there are two main factors which must be considered, viz.:

1. The immediate field of vision for the task at hand
2. The change in the effects of the surroundings with the passage of time

With respect to the immediate field of vision, research has indicated that visual acuity, contrast sensitivity, and perception of motion are at their best when the critical detail is in the center of the field of vision and surrounded by a uniform field of about the same order of brightness as the center field.

With respect to effects of surroundings influencing seeing conditions over a period of time, it is important that variety of the right kind be present if desirable results are to be obtained. In industry there is plenty of variety, but unfortunately it is usually the wrong sort where differences of contrasts and brightnesses cause distraction. Color has such an influence on seeing conditions, it is necessary to consider both decoration and lighting together as an interdependent pair. The important part that color can play in creating a successful seeing system will be discussed under Relation of Light and Color.

In examining the causes and remedies for uncomfortable and unsatisfactory lighting conditions as given in Table 13-25, it is essential to note that control of light is of primary importance not only where it leaves lighting equipment but also where it is reflected from surfaces.

Table 13-25. Factors Affecting Lighting Conditions

Cause of uncomfortable and unsatisfactory light	*Remedy*
. Insufficient illumination on the work for the seeing task involved. Remember that brightness relationships are more important to good seeing conditions than the highest foot-candles for the least wattage.	1. Sometimes a greater illumination level may be the only agency to make one see enough. It takes about four times as long to perceive small detail under 2 ft-c than it does under 100 ft-c. For a 1:10 ft-c ratio the time is about twice as long. See How Much Lighting Is Enough for Optimum Seeing.
. Direct glare caused by bright light in the range of vision. Glare results at any and all intensities where unsupported by proper levels of total field brightness to stabilize adaptation. The eye receives clear impressions of detail only in the absence of glaring light. Glare is caused by too much light in the worker's eyes compared to that on the work. Discomfort from a light source of fixed brightness increases with its visible area and, vice versa, the comfort increases with a reduction of source brightness.	2. *a.* Shield lamps properly. Avoid bare lamps in continuously occupied areas. *b.* Mount lighting fixtures as high as practical. The higher the mounting, the less the glare effect. If the mounting height is doubled, three or four times the brightness of the source may be tolerated. *c.* Increasing lighting intensities helps, but the foot-candles must be increased 10 times to stand doubling the brightness of the light sources. *d.* Best solution is to have a low-brightness broad-distribution light source. Comfort from a light source of fixed brightness increases as its visible area becomes larger. *e.* Make the lighting installation as inconspicuous as possible. Glare effect is multiplied by the number of lighting units visible from any work position. What may be suitable for a small office may be very uncomfortable in a large room.
Direct daylight glare caused by improper placement of work with respect to sunlight.	3. *a.* Properly shade windows. *b.* Shift working surfaces in such a way that the natural light falls on the working plane and away from the worker's eye.
Reflected glare caused by reflections from polished metals, glossy paper, or any material possessing a sheen.	4. *a.* Position light sources so as to keep reflections away from the eyes. *b.* Again, the best solution is a large-area low-brightness source.
. Reflected daylight glare caused by natural light that bounces from the work plane to the eyes.	5. *a.* Shade the source. *b.* Provide a high enough artificial-lighting-intensity level to offset reflected daylight.
. Specular reflection from machine surfaces which creates direct or diffused images of the light source on the work, polished furniture, and other shining surroundings	6. *a.* Reflections may be reduced by increasing the general level of illumination with low-brightness light source. *b* May be corrected sometimes by changing the mounting height of the offending units. *c.* Avoid the use of bare lamps.
Dense shadows caused by a workman on piece of equipment cutting off the light	7. Large, closely spaced units or continuous rows shine around objects and erase shadows.
Range of brightness within the visual field is too great. While the eye focuses on objects directly before the eye, it does a partial job of seeing masses well to the side of the direct line of vision.	8. *a.* Avoid competition between the nerves in the eye by keeping the brightness range between the work and the surroundings within reasonable limits—5:1 if possible. *b.* Splash enough light on the side walls to hold a ratio of at least 10:1 or better. May look a bit inefficient by calculation but worth much more psychologically.
. More light at the eyes than on work caused by improper placements of light source.	9. *a.* Angle lighting may cure bright surface jobs. *b.* Vertical or horizontal local lighting may solve some inspection problems. *c.* Install local lighting where needed.
Unpleasant surroundings, dingy, gloomy atmosphere. You get fooled by uncomfortable illumination even if the lighting intensity is adequate. Lighting cannot be evaluated by simple seeing.	10. *a.* Where the ceilings serve as a secondary light source, such as in semi-indirect or indirect lighting, the ceiling should be finished a flat white. Avoid the use of glossy paints because the shiny surfaces cause specular reflections of light sources. *b.* Walls should be colored because they are usually the background against which the task is viewed. Finishes will be discussed under Relation of Light and Color. *c.* Floors should be light—the lighter the finish of the floor covering, the higher the

Table 13-25. Factors Affecting Lighting Conditions (*Cont.*)

Cause of uncomfortable and unsatisfactory light	*Remedy*
	efficiency of the lighting system. The reflected light back to the ceiling helps relieve brightness contrasts between the luminaires and the ceiling. *d.* Desk tops should be dull finish and light in color. *e.* Plate glass should never be permitted to be placed on any desk top.
11. Improper maintenance. Lamps age and blacken and give out less light. Dirt and dust reduce reflecting and transmitting qualities of the fixtures and reflecting surfaces.	11. Five musts for proper maintenance. *a.* Clean lamps and fixtures frequently. *b.* Repaint walls and ceiling regularly. *c.* Replace burned-out lamps promptly. *d.* Maintain proper circuit voltage. *e.* Establish a definite maintenance program. Very few plants spend enough on lighting maintenance. Keeping the lighting system in best condition more than pays for itself. This will be discussed further under Economic Factors.

Summarizing the information given in Table 13-25, the basic considerations according to which lighting should be designed and criticized are as follows:

1. There should be enough light, and it should be suitably distributed on the surface to be seen.
2. There should be no glare which causes discomfort to the eye and affects its ability to see.
3. Any shadows should be agreeable, revealing rather than hiding. We depend upon shades and shadows to show form of solids. Any shadow that does not reduce the illumination more than 20 per cent will hardly be noticeable. One that causes more than a 50 per cent reduction exceeds good practice.
4. The surrounding field should be uniformly bright and equal to or less but never more than the central field brightness. Always have more light on the work than at the eye.
5. The central and surrounding visual field should be so colored as to give a pleasing sense of variety, while at the same time holding the brightness levels within reasonable limits—10:1.
6. The color of the light should be suited to the object illuminated by it. Be critical about colors of interiors. When color judgment is an important consideration, do not permit personal preferences to dictate selection.
7. The lighting installation should be as inconspicuous as possible or designed to contribute materially to the attractiveness of the environment.
8. The lighting installation should be as comfortable, efficient, economical, easy to maintain and as flexible as conditions permit.
9. Comfortable lighting is always important. Disturbing reflecting brightnesses from machines and processes are often encountered even though the product itself may be dull finish.

One of the salient features which must be recognized in industrial lighting is the relationship between the lighting of the work and the lighting of the surrounding areas. The lighting of the surrounding areas may often prove irritating or annoying even when one is not looking directly at them. The nerves of the eye compete with each other. While the eye focuses on, and sees well, objects directly before the eye, it also does a partial job of seeing masses well to the side of the direct line of vision.

Nerves in side walls of the retina warn you of the presence or approach of objects from the side. One may have to turn his eyes to recognize the object, but without turning, one is conscious that something is there. If the light in the side areas is strong, the side nerves of the eye will be calling for a small pupil aperture to restrict the admission of light. If, at the same time, the direct object of vision is not well lighted, the main object nerve will be calling for a large aperture. These contradicting demands tire the eye and make you restless to have the triangle solved.

How much energy is actually wasted when one attempts to work or play in anything but comfortable and adequate lighting is graphically illustrated by the following example.

Suppose you drive an automobile on a bright sunny day over a 50-mile stretch of straight road without heavy traffic. At the end of the ride you notice no particular exhaustion. But take the same automobile, the same road, and make the same drive at night in a fog. After 50 miles of this you know you have done some work. You have gripped the wheel, tensed your muscles, strained your whole body, and used up a tremendous amount of energy trying to see. The only actual difference between the two cases has been the amount of light available for seeing.

Seeing conditions affect employee efficiency and morale. **The benefits claimed for good seeing and lighting conditions are**

1. They enable one to see faster and do more accurate work.
2. They make seeing easier and minimize eyestrain and fatigue.
3. They improve labor conditions, encourage the use of floor space, and promote cleanliness and safety.

The wide range of effects associated with seeing are not an arithmetical summation of a series of different effects. Some of the advantages claimed for good lighting are supported by scientific evidence as discussed above, while others can be justified by logical inference and practical experience.

Some of the things the individual can do toward making the seeing tasks easier are listed below:

Avoid Glossy Finishes. *Many people needlessly abuse their eyes by insisting on plate-glass tops for their desks.* In practically every office where the occupants complain of inadequate or uncomfortable lighting there will be found high local brightnesses that are inevitable with the use of highly polished or glossy surfaces. A beautiful mahogany desk with a glass top is as bad as could be found; yet the occupants rebel at the recommendation that the glass be removed and the furniture be finished a light flat color to help the visual task. In the plant, also, light finishes on the machinery, the walls, the ceiling, and the floor can play an important part in making the visual task much easier. (See Relation of Light and Color for further discussion.)

Avoid Abuse of the Sun on the Eyes. Sunlight is very beneficial to the eyes and health, but it is necessary to know how to use sunshine to get the most out of it. Abuse of the sun on the eyes may cause great damage. No matter how suddenly you are plunged into darkness, there is no pain, but time must be given for the pupil to enlarge sufficiently for the low-intensity level. The converse happens when you go out into strong sunlight from an area where the lighting level is low. There is a feeling of eyestrain because the decreasing of the pupil (the drawing together of the shutter in its attempt to protect the eye against sudden brilliance) requires considerable time. The sudden contraction of the iris muscle is painful.

If on going out into bright light the eyes are directed downward for two or three minutes, while the size of the pupil is changing, the eyelids and eyelashes will protect the eye from the excessive light until accommodation is complete. Following this simple procedure, one may step from comparative darkness to bright light without the slighest discomfort.

The eye can be strengthened in its light tolerance by judicious exposure to light.

Avoid Wearing Sunglasses Except When Necessary. The promiscuous wearing of dark glasses has become a fad in recent years. As useful as sunglasses are, they should be worn only when necessary. They are needed when eyes are exposed to bright direct sunlight or reflected light from highways, pavements, water, or sand. They are not necessary indoors, in the shade, outdoors on a cloudy day, or for driving a car at night.

It is also important to note that dark glasses protect the eye only from visible and ultraviolet rays. The ultraviolet rays can be harmful to the eye and cause a painful inflammation of the outermost layers of the eyeball (conjunctiva or cornea). Sunlight also abounds in infrared or heat rays. The eye itself acts as a strong convex lens with the result that the infrared rays are focused on one spot in the eye and can cause "eclipse blindness" if the direct rays of the sun are viewed for some time. These rays are not held back by dark glasses to the same extent as visible and ultraviolet rays.

The preferred type of sunglasses for beach wear are ones having green or bluish green lenses. These colors absorb both the short ultraviolet and some of the infrared rays.

Smoke- or flesh-colored lenses are the best type for people who are exceptionally sensitive to the dazzle of reflected sunlight. These diminish the quantity of light more or less uniformly over the entire range of the spectrum.

When sunglasses are not necessary, take them off. Wear them only when the eyes are exposed to bright light or reflected glare.

Avoid Too Many Motion Pictures in Improperly Lighted Theaters. The bright motion-picture screen amid the very dark surroundings in most theaters presents very poor and unsatisfactory seeing conditions. Looking at a motion picture is a trying task even for normal eyes because of abominably high brightness ratios of 1:1,000 and higher on a relatively small bright area against a large black background. If viewing the screen were really a critical seeing task, it would be unbearable owing to the very unpleasant and trying contrasts.

It is possible to supply some light to the immediate surrounding without affecting the desirable contrasts in the picture itself. Seeing would then become easier and more effective. It is time the motion-picture industry realized the very poor seeing conditions usually encountered in most theaters and changed to lower brightness contrasts.

Establish Good Reading Habits. Despite the fact that today we have large better print, blacker ink, better paper, and finer illumination, the number of people who experience discomfort when they read is greatly increasing. The cause for this is not always inadequate or uncomfortable lighting conditions. Most people form bad reading habits such as

1. Reading with the body in lying or a strained uncomfortable position. Sit properly and hold the book toward the eyes. The proper distance for reading is 14 to 16 in.

2. Reading when sick or very tired and when one should be sleeping. While reading is a relaxation compared to most activities, it is no substitute for sleep and rest.

3. Reading when one is tense from hurry, fear, or worry. Lack of relaxation tenses the muscles, pulls the eye out of perfect focusing, and interferes with the normal functioning of the brain.

4. Reading to excess when it is not possible to have the print reasonably stationary, as on a train or in an automobile. The eyes under these conditions are subjected to continual fixation and a tremendous reduction in clarity of sight.

5. Reading from highly glazed paper, colored paper that is printed with contrasting ink, or other blurred or poorly printed material.

6. Skimming over a page will cause trouble because the eye is used when only partly focused, and if skimming is followed to excess, the ability to produce a complete focus will be lost, and dim or blurred vision will result.

7. Do not stare. If you have formed a habit of looking too fixedly at objects, begin to blink naturally. It does not interfere with vision and actually increases the amount of time you may actively see.

All functions of the body and mind are performed through the use of nervous energy. When they are done easily and normally, the amount of energy consumed is small. To read to best advantage avoid the bad reading habits listed above, and arrange the light so that it is adequate and comfortable.

Arrange the Office to Make the Best Use of the Lighting. Arrange the desks and working surfaces wherever possible so that (1) the fixtures are positioned with the lowest brightness area of the lighting equipment exposed to vision, (2) the reflection of light from surfaces in the work area is directed away from the eyes, and (3) worker does not face a window directly. When the eyes are adjusted to indoor intensities outdoor glare is extremely uncomfortable.

Do Not Blame All Ocular Discomfort on the Lighting. It is erroneous to conclude that all ocular discomfort and headaches are caused entirely by poor lighting conditions. Any person who is healthy, has been trained to see properly, is normal in all physical and psychological aspects, and who has normal or properly corrected vision is not likely to experience prolonged discomfort unless the lighting level is very inadequate and/or the over-all lighting conditions are very poor. There are over 20 well-known conditions in the body that may cause headaches. Ocular discomfort may result from any one or combination of the following:

1. General fatigue from any cause, physical or psychological, such as improper diet, hunger, muscular tiredness, physical defects, debilitating effect of noises, poor posture, etc.

2. Physical disorders, sinus and kidney trouble, venereal diseases, allergy to certain food, etc.

3. Emotional disturbances, such as excitement due to overwork, mental depression, nervous breakdown, etc.

The above causes of ocular discomfort are just as common under natural lighting as artificial lighting. Poor lighting conditions can and do contribute toward the difficulties by reducing the resistance and thereby increasing vulnerability.

The important thing to remember is that many conditions may cause periods where the eyes tire easily and feel strained without having very much wrong with the lighting system or anything permanently wrong with the eyes. At times, lighting and the eyes do cause headaches but not nearly so often as is generally supposed. See your physician before the oculist.

Some Things That the Architect and Engineer Can Do Toward Making the Visual Task Easier. The architect and engineer can make the visual task much easier by avoiding the use of

1. Long narrow rooms
2. Glossy paint on ceilings and side walls of room
3. "Hammered"-glass partitions and skylights
4. Glass-block walls
5. Decorations that are dark in color
6. Machine finishes of high-gloss black enamel or low-contrast colors

Facts Concerning Factors That Affect Lighting and Seeing. Some of the most important facts concerning factors that affect lighting and seeing are listed below.

1. Nature in her kinder moods provides ideal lighting conditions. The best light is uniform and diffused, such as that reflected from a cloudless northern sky. With this light there are no shadows, no high lights, no glare, and no reflection.

2. Eyestrain increases as the distance between the eye and the object decreases.

3. It has been stated that a decrease of illumination from 100 to 1 ft-c triples the fatigue.

4. Direct rays less than 20 to 30 deg from the line of vision are especially likely to create glare. The discomfort effect of a glare source is determined chiefly by the relation of its brightness to that of the background.

5. Glare causes a decrease of visibility. The effect of constant glare is to waste light—approximately 85 per cent when the glare source is 5 deg from the line of vision, 75 per cent for 10 deg, and 60 per cent for 20 deg.

6. When the vertical plane is of chief interest to the workers, it is impossible to produce a high illumination relative to that produced on the horizontal plane at the same point by means of general lighting *only* without undue glare.

7. Factors that affect glare are as follows:
   - *a. Area.* Area increases in direct proportion to the area of constant brightness source.
   - *b. Brightness.* From a comfort standpoint, doubling the brightness of the source is about the same as quadrupling its area.
   - *c. Distance.* For a constant size of glare source, the resultant glare will decrease inversely as the square of the distance. It also appears as though the effect of reflected light varies inversely as the square of the mounting height.
   - *d. Angle.* Veiling effect varies inversely as the square of the angle between source and line of vision.
   - *e. Surroundings.* Glare varies inversely with the relative brightness of surroundings raised to the 0.6 power.

To summarize, the discomfort glare varies according to the following formula:

$$\text{Glare factor} = \frac{A \times B^2}{D^2 \times L^2 \times S^{0.6}} = \frac{A \times B^2}{D^2 \times L^2 \times F} = \frac{(CP)^2}{SA \times D^2 \times L^2 \times F}$$

where A = apparent area of source, sq in.
B = brightness of source in foot-lamberts ÷ 1,000

D = distance in feet from source to eye + 10
L = angle in degrees above line of vision ÷ 10
S = surrounding brightness in foot-lamberts ÷ 10
F = foot-lambert factor
CP = candlepower in direction of the eye

8. Correct provision of artificial seeing conditions can be provided only by coordinating the various diverse effects so that the job stands out well and has a pleasing appearance.

Relation of Light and Color

Industrial-plant lighting should be designed, installed, and maintained to meet the following objectives:

1. To make the work on the eyes easier.
2. To provide more and better light to industry for the least expenditure of labor and materials.
3. To improve morale among workers by enabling them to work with speed and precision without eyestrain and with less nervous tension This is especially important for those tasks which must be performed continuously over prolonged periods of time.

It is being recognized more and more that seeing is not entirely benefited by greater and greater light intensities. The lighting level is important, but seeing also depends upon other conditions for perception and visibility. The general lighting system is therefore not limited to the installation of light sources alone. Color is important to everyone who sees, and the surfaces on which the light falls are very significant. Everything seen is subjugated to two fundamentals—brightness and color. When light strikes an object, some wavelengths may be absorbed, some may be transmitted, and some are reflected. The rays that are reflected constitute the color we see.

Light, sight, and paint are the primary tools for seeing. Paint used to cover walls, ceiling, floors, and machinery has an influence on seeing conditions and is so important that planning a set of conditions for seeing should include both lighting and painting taken together as an interdependent pair. Coupling scientifically applied colors with adequate lighting can solve many vision problems that neither one method nor the other could successfully solve by itself. It may at first sound presumptuous for the electrical engineer to be involved in the specifications for the painting of the space, equipment, and machines he has been asked to light. But the use of color has been found to be of such an immense value in giving clearer vision and preventing eye fatigue, it is the only logical procedure if the seeing conditions are to be made as good as possible.

It is not suggested that adequate seeing conditions will make the work easy and eliminate the need for effort; they will, however, so influence the workers in industrial plants that they will be stimulated in the performances of their tasks and will maintain better their rate and quality of work over the entire working period.

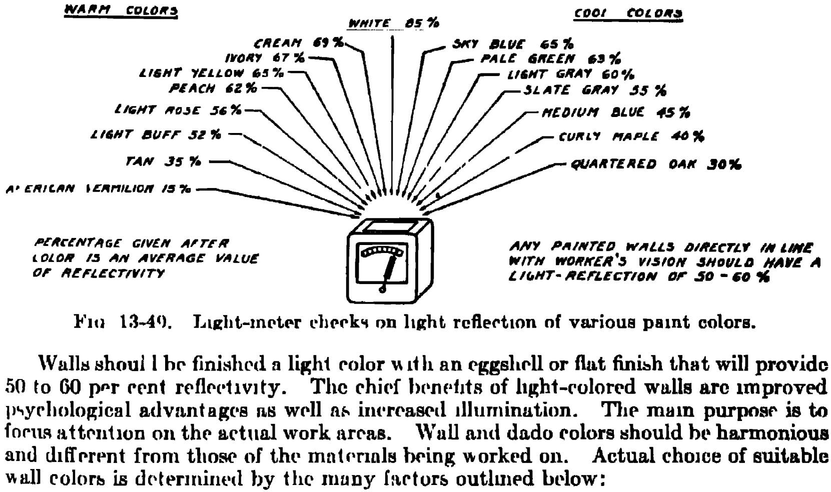
When considering the subject of industrial-plant painting, the aim is more than upkeep maintenance. The basic reason for painting any plant interior should be to realize the most out of both natural and artificial light. Painting in industrial plants is not interior decoration. The use of color is to establish seeing conditions that automatically make the seeing task easier and avoid distraction. Other advantages gained by proper selection of colors are

1. It improves the appearance of the plant.
2. It aids sanitation and "good housekeeping."
3. It reduces fatigue and absenteeism.
4. It cuts accident toll and reduces spoilage and rejects.
5. It fosters better employee-management relationship.

Three guiding factors in coordinating lighting and painting are reflectivity, finish, and color. The reflectivity of various paint colors is given in Fig. 13-49. It has been shown that coverage is an important factor in that thin coats of paint have much lower reflectivity than heavy coats. Recommended coverage is usually not more than 460 sq ft per gal.

Generally flat or eggshell finishes are desirable over glossy surfaces. The former will result in better distribution of light and brightness, while the latter cause specular reflections from the light sources and annoying glare when in line of vision. All the advantages of interior industrial painting generally stem from the fundamental fact that properly painted ceilings and walls greatly increase the lighting efficiency, comfort, and see-ability.

White paint reflects more light than any other color, and for this reason most commercial and factory interiors should have the ceiling and upper walls painted with white to provide a high reflection factor of 80 per cent or more. (The exception would be those rare cases where the location of the operator's work forces him to look directly upward.) Light ceilings are essential where indirect or semi-indirect lighting installations are made because the ceiling is a secondary reflector. In all types of lighting installations, the high reflection factor of white ceilings will increase the illumination, provide light diffusion, reduce shadows, and, in general, improve seeing comfort.



PERCENTAGE GIVEN AFTER COLOR IS AN AVERAGE VALUE OF REFLECTIVITY

ANY PAINTED WALLS DIRECTLY IN LINE WITH WORKER'S VISION SHOULD HAVE A LIGHT-REFLECTION OF 50 - 60 %

FIG 13-49. Light-meter checks on light reflection of various paint colors.

Walls should be finished a light color with an eggshell or flat finish that will provide 50 to 60 per cent reflectivity. The chief benefits of light-colored walls are improved psychological advantages as well as increased illumination. The main purpose is to focus attention on the actual work areas. Wall and dado colors should be harmonious and different from those of the materials being worked on. Actual choice of suitable wall colors is determined by the many factors outlined below:

1. *Physical Dimensions (Size and Height) of the Area.* In small areas, walls assume greater importance than in larger areas. They should be painted in such a manner as to provide variety yet be inconspicuous. The contrast should be color and not brightness. In a large area, the equipment and machinery will provide the variety, and the walls may be a relatively unimportant background. Certain colors which may look attractive on a color card may prove too bright or distracting when actually applied on a large area. The larger the area, the softer the color should be.

2. *Color of Natural Lighting.* Daylight varies greatly in spectral character with the time of day and with the point of compass. Even northern light, which has the st diversity in intensity, varies from a bluish white when the sky is clear to practically white when the sky is overcast. For typical characteristics of natural light see Table 13-26. When daylight is predominant in an area, complementary wall colors will usually give the best results.

3. *Color of Artificial Light.* The color quality of various light sources was given in Table 13-21. These qualities, together with a listing of the complementary colors, are given in Table 13-26. The color of light from any fluorescent installation is different from the accustomed yellowish-white color of incandescent-filament lighting. The color of interiors is important. For the effect of the type of lighting on wall colors as classified by a large group of observers, see Table 13-27. The reflection factor of a

given surface may vary for different light sources. The variation depends upon the reflection characteristics of the surface and the color content of the lamp output. The effect of the type of lighting on the human skin is given in Table 13-28. The psychological reactions which different persons have toward the various light sources and colors present a problem which cannot be ignored if the result is to be a comfortable and satisfactory interior and lighting scheme.

The color of lighting used in grocery stores, kitchens, cafeterias, and restaurants must be given due consideration. The daylight 4500 and 3500°K white fluorescent lamps in general have proved unsuitable to foodstuffs. The "soft-white" fluorescent lamp which has an approximate color temperature of 2800°K is kind to the complexion, raw and cooked food, and to many displays of wearing apparel. The effect of types of lighting on meats, fruits, and vegetables is given in Table 13-29.

Always choose paint colors under the same type of lighting with which they are to be used.

4. *Atmospheric Conditions.* No matter what type of light source is employed, brightness, as well as color, plays a significant part in the final result obtained. Low-intensity fluorescent lighting will almost certainly be cool, while if the illumination were increased to 50 ft-c, the result would be far more stimulating.

Table 13-26. Characteristics of Natural and Artificial Light

	Natural light	
Principal direction of light	Predominant color of light	Complementary color (contrasting hues)
Eastern	Neutral in color	Warm gray, sunlight
Southern	Yellowish tinge	Shades of blue
Western	Reddish tinge	Cool green
Northern	Cool blue	Light buff, peach
	Artificial light	
Type of light source	Predominant color of light source	Complementary colors*
Incandescent filament	Yellowish white	Light blue, light green, bluish green
Soft white fluorescent	Warmest in hue of all types of white fluorescent lamps (rich in red tones)	Neutral gray, grayed green, grayed blue
3500°K white fluorescent	Yellowish green cast	Warm gray, beige, peach
4500°K white fluorescent	Greenish blue cast	Buff, coral
Daylight fluorescent	Cold bluish	Tan, coral
Combination incandescent and 3500 or 4500°K fluorescent	About the same as soft-white fluorescent	Same as soft white fluorescent
Mercury	Bluish green	Light purple, reddish gray

* Complementary colors are known as contrast colors. If a disk is divided into differently colored sections and is rotated rapidly, different color effects will be experienced according to the colors used. If, for example, only red and yellow sectors are used, the rotating card will appear to be orange. The two colors will bend to produce an intermediate color. If the two sectors are red and green, both colors will disappear and the rotating disk will look gray. Colors that cancel each other out in this manner instead of blending are called "complementary" colors. Each and every color has a complementary color, i.e., yellow and violet—the sum of red and blue; red and green—the sum of yellow and blue; blue and orange—the sum of red and yellow, and so forth for all the secondary colors.

Among the many odd attributes of color is the fact that some hues give the feeling of warmth and some of coolness. In general, colors in the blue end of spectrum tend to create a cool atmosphere and will have an effect equivalent to an appreciable fall in temperature. On the other hand, colors in the red end of the spectrum can compensate for the effects of a chilly atmosphere and can create a warmer, more friendly atmosphere. Ivories and creams, frequently used, are classed as warm tones but have been found to become tiresome. Red and orange colors irritate, hence are believed

Table 13-27. Effect of Type of Lighting on Wall Colors

(Illumination level, 50 ft-c)

Color-conditioning paint*	Daylight fluorescent	3500°K white fluorescent	Soft-white fluorescent	Incandescent filament
Ivory	Faded gray, unattractive	Slightly greenish gray	Slightly yellow	Cream
Rating	Poor	Good	Preferred	Good
Sunlight	Bluish yellow	Slightly bluish	Vivid cream	Rich yellow
Rating	Fair	Preferred	Good	Good
Peach	Slightly pink	Normal, slightly cold	Normal, slightly pinkish	Normal, same as white light
Rating	Good	Fair	Preferred	Good
Light rose	Purplish pink	Yellowish	Normal, vivid pink	Pinkish orange
Rating	Fair	Good	Preferred	Good
Equal parts of light green and white	Grayish green, cold	Whitish gray green	Pale green	Pale green
Rating	Fair	Good	Preferred	Fair
Light green	Fresh bluish green	Greenish gray	Slightly grayish	Yellowish pale green
Rating	Preferred	Good	Good	Good
Equal parts of light blue and white	Grayish blue, cold	Bluish green	Pale blue	Whitish blue
Rating	Poor	Good	Good	Fair
Light blue	Bluish green	Grayish green	Slightly grayish	Grayish faded blue
Rating	Good	Preferred	Good	Good
Equal parts light gray and white	Bluish white, cold	Cold gray	Warmer, pale gray	Off shade of white
Rating	Poor	Poor	Fair	Good
Light gray	Cold gray	Faded gray	Warm gray	Warmer gray
Rating	Poor	Poor	Fair	Good

Color-conditioning Trim and Dado Colors*

Wall colors	*Trim and dado colors*
Ivory, sunlight, or peach	Tan
Light rose	Deep rose
Green and light green	Medium green and deep green
Blue and light blue	Medium blue and deep blue
Gray and light gray	Medium gray and deep gray

* The vividness of sunlight, peach, and light rose may be toned down the same as green and blue, *i.e.*, equal parts of these colors and white.

Table 13-28. Effect of Type of Lighting on Human Skin

(Illumination level, 50 ft-c)

Description of skin	Daylight Mazda F	3500°C white Mazda F	Soft-white Mazda F	Incandescent filament
Untanned skin	Pale, slightly gray	Sallow, slightly greenish for older skin	Enhanced	Yellowish, appearance slightly tan
Rating	Fair	Acceptable	Preferred	Good
Tanned skin (medium)	Grayish tint	Intensified greenish tint, very sallow	Healthy glow	Intensified reddish tint
Rating	Fair	Fair	Preferred	Fair
Deep pigmentation	Intensified grayish tint	Intensified greenish tints very sallow	Healthy glow	Deep rich brown
Rating	Poor	Fair	Good	Preferred
Sunburned skin (red)	Slightly reddish, deep-purple tint	Tanned appearance	Slightly reddish	Fiery red
Rating	Fair	Preferred	Good	Poor
Untanned skin, light make-up	Overemphasized make-up in contrast to skin	Make-up grayed, sallow appearance	Blended skin and make-up improved appearance	Intensified make-up, slightly sallow
Rating	Poor	Fair	Preferred	Good
Untanned skin, heavy make-up	Further overemphasized make-up, very pale skin	Sallow appearance of unpainted skin intensified	Enhanced skin make-up	Slightly sallow
Rating	Poor	Fair	Preferred	Good

to be a frequent cause of anger. The colors in the center of the spectrum—light blue, green or yellow green—seem to be the most effective, both for the psychological and lighting factors.

The effect of warmth due to hard physical work can be compensated in exactly the same way as that of a high atmospheric temperature.

Table 13-29. Effect of Types of Lighting on Meats, Fruits, and Vegetables
(Illuminating level, 50 ft-c)

Test article	Daylight Mazda F	3500° white Mazda F	Soft-white Mazda F	Filament (100 watts)
Red meats	Poor	Fair	Good	Preferred
Dressed chicken	Poor	Fair	Good	Good
Butter	Poor	Good	Good	Preferred
Chocolate	Poor	Fair	Fair	Good
Bread (brown crust)	Fair	Good	Good	Good
Oysters (opened)	Poor	Poor	Fair	Preferred
Parsley	Good	Good	Fair	Poor
Carrots	Good	Good	Good	Good
Tomatoes	Fair	Fair	Fair	Preferred
Red apples	Fair	Fair	Fair	Preferred
Onions	Poor	Fair	Fair	Fair
Green apples	Good	Good	Fair	Poor
Squash	Fair	Good	Preferred	Good
Bananas	Fair	Good	Good	Good
Red and green peppers	Fair	Good	Good	Good
Green beans	Good	Good	Fair	Fair
Cauliflower	Poor	Poor	Good	Good
Green cabbage	Fair	Poor	Fair	Fair
Red cabbage	Fair	Fair	Good	Preferred
Corn	Good	Preferred	Good	Good
Lemons	Poor	Poor	Fair	Good
Peaches	Good	Good	Good	Good
Oranges	Fair	Fair	Good	Preferred
Plums (reddish purple)	Fair	Good	Preferred	Good

NOTE: With reference to painting, light peach has proved the most "appetizing" wall color for restaurants and cafeterias under all types of lighting. The soft white is the best type of fluorescent lighting for kitchens, restaurants, cafeterias, etc.

In such nonwork areas as corridors, washroom, rest rooms, etc., color can provide a welcome "change of pace." The color preferences of the two sexes determine the color recommendations for the respective facilities. Color of nonworker-area industrial interiors must be chosen for their "livability," and it is wise to bring the employees involved into the final decision. Men usually express a preference for cool colors while women like warm colors.

5. *Noise.* Noise has a great effect on seeing and causes a continual irritation of the central nervous system. Owing to the deleterious effects of noise, all practical measures to reduce the noise level should be taken. Even though acoustical materials cause a reduction in the reflectivity of the ceilings and walls, the loss of illumination will be more than compensated for by the increase in comfort, except where the intensity level is low for the visual tasks.

Color has played an important part in recent years through the practice of painting machinery to improve visibility. To judge from current advertising, a little paint will make any lighting system, however inadequate, a satisfactory installation. (One paint manufacturer published colored pictures of brilliantly painted machines and plant interiors with the area lighted with tin cone reflectors of ancient vintage.) Brilliant colors have no place in creating successful seeing conditions in industry, since from their very nature they introduce uncomfortable contrasts.

Bearing the above comments in mind, the following general recommendations for industrial interiors are made:

Ceilings. White or near-white paint should be used on ceilings with the lighting installation arranged to blend with the ceiling so as to present the least possible distraction. Where direct-type lighting is used, the finish of the ceiling becomes less important. When factory ceilings are excessively high, a gloss white may be satisfactory. Where such factors as dirt resistance and washability must be considered, a glossy finish will give the best performance; however, never use a glossy finish where light may be reflected to the eyes.

Structural. A medium tint of bluish green or pea green on structural beams will give a feeling of support. If the number of exposed beams is large, aluminum paint may be satisfactory, while white is preferred.

Upper Walls and Columns. Grayish tints having a reflection factor of 50 to 60 per cent, will be most satisfactory on wall areas. A dado may be used to advantage especially in the smaller shops. Walls should be finished in hues to complement either the exposure or the type of artificial light, whichever produces the most predominant lighting in the area.

Lower Walls and Columns. Colors blending with upper walls should be used on lower walls and columns. Avoid colors that go "flat" under the lighting system. Use color for recognition for such items as markers or traffic aids, fire exits, safety precautions, etc.

Floors. A great deal has been said lately about painting factory floors in light colors "to aid in light reflection." Except where it is desirable to reflect light upward under large horizontal surfaces such as aircraft wings, a not too bright color of medium depth is recommended with "traffic stripes" separating the working areas from those used for the movement of materials. These traffic stripes can be as bright as necessary to serve as "keep-clear" warnings. Some existing floors cannot be successfully painted because they are oil soaked or otherwise in such condition that painting would present an almost impossible maintenance problem.

Machines. The machines should be painted in shades to delineate machine parts and danger areas and promote visibility and safety. Avoid using different colors too profusely, or they will loose their effectiveness as contrast mediums. The color scheme of the walls, floors, and machines should present a harmonious pattern limited as to similarity. On no account should a uniformly colored light finish be used over machines, walls, and even floors, as they will give an extremely monotonous appearance.

Three-dimensional seeing, a science of color and light for better vision in industry, offers a solution to the problem of improving industrial seeing conditions.

Desks. Desk tops need a higher finish than the 5 to 7 per cent prevalent today. Thirty-five per cent is the minimum recommended with the desk sides higher in reflectance because the vertical illumination is, in almost all cases, much less than the horizontal.

The evaluation of reflection factors in finishing ceilings, walls, and equipment will result in better light utilization and more desirable ratios. This will, of course, depend on a proper analysis of practicability. There are many industrial operations which are not sufficiently clean to justify light-colored finishing, such as, for example, some chemical-plant areas, foundries, etc., where a coat of light paint may last little longer than the time to put it on. Here the lighting system must be designed to give the illumination required from direct-type lighting units which properly shield the lamp source. However, in the majority of industrial plants, the most satisfactory system proves to be a combination of adequate lighting intensity and a simple color scheme having a proper reflectance value. The result will be a well-planned seeing condition.

While each plant presents certain individual problems, the general plans developed through the systems of "color conditioning" and three-dimensional seeing serve as guides in applying acceptable color principles.

Some of the important facts concerning the relation of light and color are listed below:

1. Lighting for seeing also involves paint for seeing. Color plays an important

part in every industrial-plant installation. Applications vary widely from a simple matter of personal preferences for private offices to the more complicated industrial inspection tasks where small color differences must be detected.

2. Color appearance of objects depends not only on the reflectance characteristics of the objects themselves but also on the color content of the light with which they are illuminated. The appearance of materials having complex spectral reflectance characteristics, when illuminated by fluorescent sources which have complicated energy distributions, is often impossible to predict.

3. Light greatly outstrips paint in ability to produce variations in color effects. Tables 13-26, 13-27, 13-28, and 13-29, indicate some of the changes that take place under filament incandescent and three types of "white" fluorescent lamps.

4. The choice of industrial finishes depends on many psychological and practical viewpoints. The four most important aspects of color in industrial lighting operations are

a. The finishes of ceilings, walls, and machines to provide a pleasing background of brightness and color for optimum visual efficiency and comfort.

b. The finishes of work and danger areas for safety and visual efficiency.

c. The provision of appropriate color-quantity lighting for inspection tasks involving the discrimination and evaluation of color.

d. The color scheme should be simple. The large number of people using the area and the many jobs carried out make durability an important aspect, and only a simple scheme can be durable.

5. Yellow, red, and blue are the primary colors. From these all the hues of the spectrum can be produced, but none of the primary colors can be obtained by any mixture.

6. Office equipment is sadly in need of reform. The majority of typewriters, accounting machines, etc., are finished in a high-gloss black enamel. There is no reason why such machines should not be finished in a light color and have a finish to prevent undesirable reflections. The use of colored paper always reduces visibility. Glossy finishes on paper are also undesirable. Blotting pads and desk tops should be light in color and free from undesirable reflections.

7. One of the principal factors of importance to good seeing conditions is the general "atmosphere" of the surroundings—brightness, color, variety.

8. In inspection work where the products must be held to narrow color-tolerance limits, the best lighting system is one which is rich in the spectral region where there is maximum absorption (minimum reflectance). This will accentuate the differences in color. The source should produce light throughout the visible spectrum and be so located that specular reflections are avoided. For detecting small color differences Table 13-30 gives the best type of light.

Table 13-30

Colors	*Type of lighting*
Blue, purple, violet .	Incandescent filament
Red, pink	Daylight fluorescent
Green, yellow	3500°K white fluorescent

Observations on the Relations of Lighting Effects and Psychological Reactions

In 1845, the first lighting survey was conducted at the President's Mansion (White House) in Washington, with recommendations submitted to Mrs. James K. Polk. As a result, some 18 kerosene lamps replaced 150 tallow candles in the East Room, thereby approximately doubling the lighting intensity and reducing daily lighting expense from $8.75 to $2.11. A total of 416 candles lighted the White House at the time. When the remarkable "coal oil burners" were installed, there were many who marveled, but those were the days of *fractional* foot-candles--not eye comfort.

Lighting standards have advanced greatly since then. Thirty years ago, the first industrial lighting code of the Illuminating Engineering Society recommended, with considerable temerity, a lighting intensity of 1.25 to 1.35 ft-c. The reasons for the low foot-candle level were not based on the needs or habits of the human eye but rather on the prohibitive expense, excessive heat from the light source, detrimental glare of high candle-power sources, and the inadequacy of the wiring.

Today, the lighting problem in industrial plants is dynamic and changing in importance and scope. Dominant human factors, including inherent differences in the optical and neural apparatus for seeing, defects from injury or disease, age of the eyes, previous light education, etc., all produce a considerable range in solving lighting problems for various conditions and individuals.

In giving attention to the needs which different persons seem to feel for illumination, it has been observed that there is to some degree a correlation existing between the nature of a person, the type of work he enjoys or is qualified to do, and the quantity and quality of lighting he finds satisfactory, regardless of whether or not it is a "correct" lighting job under the modern practice type of installation.

We are fortunate in that persons engaged in the same type of work or activity usually have enough in common to make satisfactory the use of some general type of lighting for the entire group. To provide special lighting effects for each individual would be very impractical and prohibitive in costs; however, the individual should be studied as a means of learning the characteristics of the group.

The characteristics of individual groups and the needs they seem to require regarding illumination are outlined in Table 13-31. The psychological reactions which different types of people give to each of the more common types of lighting effects are outlined in table.

ILLUMINATION LEVEL

FIG. 13-50. Types of people and their choice of lighting effects.

Figure 13-50 shows a pyramid divided into five sections of equal height with each section representing a type of person. Group 1 is classified as active out-of-doors. This type of person is inclined toward muscular expression and is fond of bright sunlight. Emphasis is inclined to be placed on physical activity with mental effort being at a minimum. In supplying lighting for this group, it has been found they demand that the lamp "shine" and that it be a bright source. In many applications even bare incandescent lamps may be satisfactory. The unit should be mounted well above the line of vision as a means of reducing glare.

Group 2 is classified as active indoors. This type of people operate machines, doing work of a routine nature which requires a minimum of mental activity. Since the tasks are usually of a concentrated order, local lighting focusing attention upon a central point finds favor with this group. Open-type lighting reflectors may be used to advantage in the general lighting system in this type of occupancy.

Group 3 is the physical-mental activity type, whose thinking deals with people and material things, such as physicians, merchants, industrialists, etc. While they enjoy daylight extensively, people who perform this type of work usually prefer a soft type of uniform illumination. Their choice of artificial lighting, oddly enough, is generally an enclosed visible light source.

Group 4 is the mental activity type. Their thoughts deal with ideas and ideals. Work involving physical activity is usually foreign to their nature. The choice of artificial lighting is a low brightness source of the indirect incandescent type or the semidirect fluorescent type.

Table 13-31. The Key to Harmonized Lighting

Characteristics of the more common lighting effects	Types of people				
	Active out of doors	Active indoors	Physical-mental activity	Mental activity	Meditative
1. *Bare lamps* High brightness of light source. Radiant light, poor distribution of light producing sharp shadows and glare. Natural example: bright sunshine.	↑ Exciting active lively ←	Physical activity	Annoying	Irritating	Extremely irritating
2. *Open reflectors (rim type)* Light directed downward from fixture, high intensity of light on working plane, sharp shadows, reduced glare. Natural example: moderate sunshine.	Physical activity	↑ Concentrated physical activity ←	Physical activity	Depressingly annoying	Irritating
3. *Enclosed or shielded fixtures* Lower brightness of light source, diffused light, soft shadows, generally uniform illumination. Natural example: overcast sky or shady location.	Subtle	Mentally active	↑ Physically and mentally active ←	Physical activity	Annoying
4. *Direct-indirect fluorescent, semi-indirect incandescent* Low brightness of apparent ceiling, well-diffused light, soft shadows, high uniformity of light distribution. Natural example: late afternoon.	Dead	Subtle	Restful	↑ Mentally active ←	Physically and mentally active
5. *Indirect lighting supplemented by bright local sources* Low intensity of indirect lighting supplemented by local lighting having small but bright light sources. Natural example: twilight.	Dead	Dead	Dull	Restful	↑ Meditative ←

Group 5 is the meditative type. These people are very sensitive and usually find expression in passive thought or meditation: their interests are not akin to the commercial or industrial world. This group includes inspirational writers, musicians, etc. This type prefers a lighting effect which simulates twilight with local high-lighting on the work.

It is important to note that the distribution of people may be considered as approximately represented by the volume of the five sections of the pyramid and, even though most people are intermediate or combination types, their natural expression can be used as an index or key to harmonized lighting, which will please the various classifications or groupings of people, regardless of whether or not the electrical engineer considers the type of lighting adequate in quality and quantity for the visual tasks performed. To provide satisfactory lighting, it is necessary to impose the human factors upon calculations.

Some of the important facts concerning the relationship of lighting effects and psychological reactions are noted below:

1. The process of seeing is very complicated and much affected by the flexibility of the individual nervous system.

2. The production and control of light are physical sciences; however, lighting is also concerned with vision, seeing, and physiological and psychological effects.

3. The psychological effects of lighting are concerned with such items as attention, impression, distraction, annoyance, alertness and mental fatigue.

4. Lighting calculations and practice were, and still are, largely empirical. Our present knowledge concerning the relation of light to sight is neither comprehensive nor well understood. Only recently has the science of lighting begun to be a part of our present meager knowledge in the science of seeing.

5. Design of good lighting involves not only the physics, mathematics, and economics of light generation and control, but also:

a. The physiology of visual sensation and its related processes.

b. The psychology of the mind, which correlates, integrates, and evaluates the sensation.

6. The most important item in considering any lighting system is the ***human factor***, or the people for whom the lighting is being installed.

POWER BELTING, FASTENERS, PULLEYS, AND SHAFTING

BY WILLIAM STANIAR, M.E.

POWER BELTING

Belting is one medium of delivering a given amount of power at a low cost per unit of time which should result, provided the correct type and size are employed, in the transmission of power at a low cost per horsepower per year over a long period of useful service. The function of power belting is to transmit power economically. Therefore the user should be familiar with the characteristics and properties of the various types of belting available. Mechanical and atmospheric operating conditions vary; hence knowledge of such conditions results in low maintenance, efficient power delivery, and lengthened life of the belting and other transmission appurtenances.

Belting Types

1. Leather
2. Rubber
3. Stitched cotton duck, impregnated
4. Solid woven cotton, impregnated
5. Camel's hair, impregnated
6. Balata
7. Teon

These types vary in characteristics and atmospheric resistance based on the substance employed and the various methods of manufacture.

Leather Belting

The best leather for power belting is derived from the hides of three- or four-year-old steers. Such hides are of two classes, "packer" and "country." Packer hides are those taken from the animal in large packing houses by experts and hence are relatively free from flesh cuts. Country hides are those taken off by butchers. Belting leather is made from that portion of the hide approximately 48 in. from the root of the tail toward the head and 24 in. from each side of the backbone. This portion is known as the "butt bend." The quality of the leather is generally determined by the relation of the belting strip to the backbone center line.

Preparing the green hide for leather belting consists of (1) tanning by either the oak or mineral process, (2) cutting out the butt bend, (3) stuffing or currying the tanned butt bend, (4) cutting the butt bend into centers and sides, (5) stretching sides and centers, and (6) glazing or jacking the sides and centers.

Constructing the leather belt consists of a series of operations: (1) cutting the centers and sides into the required belting widths, (2) matching the strips for thickness, (3) scarfing and tapering the ends of the strips, (4) squaring the scarfed ends, (5) assembling and cementing by either a nonwaterproof glue or a waterproof cement, (6) pressing, (7) trimming and stamping, and (8) measuring and finishing.

The required strips are cut from both sides of the butt bend and are known as "rights" and "lefts." These strips are cemented end to end and must alternate right and left throughout the length of the belt, with all edges toward the backbone on one side and all edges toward the belly on the other. The method is to join tail end to tail end and shoulder end to shoulder end. The construction is shown by Fig. 14-1.

In cementing together two single-ply leather belts to form a double-ply belt, the ends are so arranged that each part of one lies in a reversed position to the other. The lap of a single-ply belt is made as shown in Fig. 14-2 and that of a double-ply belt as shown in Fig. 14-3.

First-quality leather belting depends upon the leather having fibers of firm texture and being free from sponginess and looseness. Leather cut within 15 in. of each side of the backbone of the hide is generally considered first quality, but modern practice tends to select belting strips from the butt bend with regard to firmness of fiber rather than definite measured limits.

Note:-All leather belts should run so that the point of the lap on the outside does not run into the wind

Fig. 14-2. Single-ply leather-belt lap.

Fig. 14-3. Double-ply leather-belt lap.

Second-quality leather belting is known as "low-cut leather" since it is cut from the butt bend beyond the 15 in. limit. It is cheaper than first-quality belting and can be used for light-power, normal driving.

Several grades and brands of leather belting are manufactured, but essentially there are four distinct types: (1) nonwaterproof oak tanned, (2) waterproof oak tanned, (3) waterproof mineral retanned, (4) waterproof combination of oak tanned and mineral retanned.

Table 14-1. Minimum Pulley Diameters in Inches for Oak-tanned Leather Belting at Various Belt Speeds

Belt thickness, in.	Belt speed, fpm					
	1,000	2 000	3,000	4,000	5,000	6,000
Single ply						
8/64	1½	2	2¼	2½	3	3½
10/64	2	2½	3	3½	4	4½
12/64	2¾	3½	4	4½	5	5½
14/64	3½	4	4½	5½	6	7
Double ply·						
15/64	5	6	7	8	9	10
18/64	6	8	9	10	12	13
20/64	8	9	11	12	14	16
23/64	9	11	13	15	17	19
26/64	11	14	16	18	20	22
Triple ply:						
28/64	18	21	24	28	31	35
32/64	20	24	28	32	36	40
35/64	22	27	32	36	40	45

Oak-tanned Leather Belting (Nonwaterproof). ***Characteristics***

1. Fabricated with hot glue.
2. Made in one ply, two ply, and three ply. Known as singles, doubles, and triples. Four ply is seldom used.
3. Widths of singles, ⅛ to 10 in.; doubles, 1 to 72 in.; triples, 12 to 72 in.
4. Not flexible when new, therefore not adaptable to small-diameter high-speed pulleys.
5. Possesses low stretch.
6. Coefficient of friction: new, 0.27 to 0.45; well worn, 0.35 to 0.60.
7. Can be made endless by manufacturer or at point of application.
8. Will not resist moisture, steam, acid, or high temperatures.

Oak-tanned Leather Belting (Waterproof). This type is similar to regular oak-tanned belting with one exception. It is fabricated with a moistureproof pyroxylin cement, and the leather is specially dressed to resist the action of moisture.

Horsepower Formulas and Tables for Oak-leather Belting (Nonwaterproof and Waterproof)

SINGLES:
Light: ⅛ in. thick, 40 lb allowable effective tension per inch width
Medium: $\frac{5}{32}$ in. thick, 45 lb allowable effective tension per inch width
Heavy: $\frac{3}{16}$ in. thick, 50 lb allowable effective tension per inch width
FORMULA:

$$\mathrm{Hp} = \frac{T \times W \times S}{33{,}000}$$

$$W = \frac{\mathrm{hp} \times 33{,}000}{S \times T}$$

where T = allowable effective tension, lb per in. width
W = width of belt, in.
S = speed of belt, fpm

Table 14-2. Horsepower Rating for Medium Single-oak Belting $\frac{5}{32}$ In. Thick, Based on 45 Lb Effective Tension

Width of belt, in.	Belt speed, fpm											
	750	1,000	1,250	1,500	1,800	2,000	2,500	3,000	3,500	4,000	4,500	5,000
1	1	1.36	1.71	2.05	2.43	2.7	3.4	4.1	4.8	5.4	6.1	6.9
2	2	2.72	3.42	4.06	4.86	5.4	6.8	8.2	9.6	10.8	12.2	13.8
3	3	4.1	5.1	6.1	7.3	8.2	10.2	12.3	14.4	16.2	18.3	20.7
4	4	5.4	6.8	8.12	9.72	10.8	13.6	16.4	19.2	21.6	24.4	27.6
5	5	6.8	8.5	10.1	12.1	13.5	17.0	20.5	24.0	27.0	30.5	34.5
6	6	8.1	10.2	12.18	14.5	16.2	20.4	24.6	28.8	32.4	36.6	41.4
7	7	9.5	12.0	14.21	16.91	18.9	23.8	28.7	33.6	37.8	42.7	48.3
8	8	10.8	13.6	16.2	19.4	21.6	27.2	32.8	38.4	43.2	48.8	55.2

These ratings are based on 165 deg arc of contact and are not corrected for the action of centrifugal force.

For light singles ⅛ in. thick, figure 90 per cent of these ratings.
For heavy singles $\frac{3}{16}$ in. thick, figure 112 per cent of these ratings.

DOUBLES:
Light: ¼ in. thick, 60 lb allowable effective tension per inch width
Medium: $\frac{5}{16}$ in. thick, 65 lb allowable effective tension per inch width
Heavy: ⅜ in. thick, 75 lb allowable effective tension per inch width

Table 14-3. Horsepower Rating for Medium Double-oak Belting $\frac{5}{16}$ In. Thick, Based on 65 Lb Effective Tension

Width of belt, in.	Belt speed, fpm												
	500	850	1,000	1,250	1,500	1,800	2,000	2,500	3,000	3,500	4,000	4,500	5,000
3	3	5	6	7.4	9	10.6	12	15	18	20	24	27	30
3½	3.42	5.8	6.9	8.6	10.3	12.3	14	17	20.8	24	28	31	35
4	4	6.7	8	10	12	14	16	20	24	27.5	31.5	35.5	39.5
5	5	8.5	10	12.3	14.7	17.5	20	24	30	35	40	44	49
6	6	10	12	15	18	21	24	30	35	41	47	53	59
8	8	13.5	15.5	20	23.5	28.5	31.5	40	47	55	63	71	79
10	10	17	20	25	30	35	40	49	59	69	79	89	99
12	12	20	23.5	30	35	42.5	47.5	60	71	83	95	107	118
14	14	23.5	28	34.5	41	50	55	69	83	97	110	124	138
16	16	26.5	31.5	39	47	57	63	79	94	110	125	142	157
18	18	30	35	44	53	64	71	90	107	123	142	160	177
20	20	33	40	49	59	71	78	98	118	139	158	177	200
24	24	40	47	59	71	85	95	118	142	166	190	212	236
30	30	50	59	74	89	106	118	147	177	206	236	266	300

These ratings are based on 165 deg arc of contact and are not corrected for the action of centrifugal force. For light doubles ¼ in. thick, figure 92 per cent of these ratings. For heavy doubles ⅜ in. thick, figure 114 per cent of these ratings.

TRIPLES:

Medium: ½ in. thick, 100 lb allowable effective tension per inch width

Heavy: $\frac{9}{16}$ in. thick, 110 lb allowable effective tension per inch width

Table 14-4. Horsepower Rating for Medium Triple-oak Belting ½ In. Thick, Based on 100 Lb Effective Tension

Width of belt, in	Belt speed, fpm										
	200	400	600	800	1,000	1,500	2,000	2,500	3,000	3,500	4,000
12	7	14	21	28	35	55	70	91	110	127	140
14	8.5	17	25.5	34	42.5	64	85	106	128	148	170
16	9.5	19	28.5	38	47.5	73	95	121	146	169	190
20	12	24	36	48	60	91	120	151	182	212	240
24	14.5	29	43.5	58	72.5	110	145	182	220	254	290

36	22	44	66	88	110	164	220	274	328	380	440
44	27	54	81	108	135	200	270	334	400	465	530
48	29	58	87	116	145	218	290	362	436	510	580
60	36	72	108	144	180	272	360	450	544	635	720
72	44	88	132	176	220	326	440	550	652	820	880

These ratings are based on 165 deg arc of contact and are not corrected for the action of centrifugal force. For heavy triples, $\frac{9}{16}$ in. thick, figure 111 per cent of these ratings.

Mineral-retanned Leather Belting (Waterproof). This type is oak leather retanned by a mineral process. The mineral process of retanning produces a leather entirely different from that created by the regular oak tannage, and it therefore has different characteristics.

Characteristics

1. Made in similar plies, thicknesses, and widths as regular oak but possesses greater power-transmitting ability ply for ply and width for width.
2. Fabricated with a cement insoluble in water, moisture, or steam.
3. The leather is treated to resist water, moisture, steam, and acids.

4. Extremely flexible in all thicknesses, therefore adaptable to high-speed small-diameter pulleys.
5. Coefficient of friction, 0.60 to 0.87.
6. Can be made endless by manufacturer or at point of application.
7. Will resist water, moisture, steam, temperatures to 130°F, mineral oil, cutting compounds, and also the action of the mists and vapors of the corrosive acids for a considerable period of time.
8. Cannot be dressed with the compounds used for oak-tanned leather.

Horsepower Tables for Mineral-retanned Leather Belting

SINGLES:

Light: $\frac{1}{8}$ in. thick, 45 lb allowable effective tension per inch width
Medium: $\frac{5}{32}$ in. thick, 50 lb allowable effective tension per inch width
Heavy: $\frac{3}{16}$ in. thick, 55 lb allowable effective tension per inch width

Table 14-5. Horsepower Rating of Medium Single Mineral-retanned Belting $\frac{5}{32}$ In. Thick, Based on 50 Lb Effective Tension

Width of belt, in	Belt speed, fpm										
	650	850	1,000	1,250	1,500	1,800	2,000	2,500	3,000	3,500	4,000
1	1.0	1.29	1.52	1.9	2.3	2.7	3.0	3.8	4.5	5.3	6.1
1¼	1.23	1.6	1.9	2.4	2.8	3.4	3.8	4.8	5.7	6.6	7.5
1½	1.48	1.92	2.3	2.8	3.4	4.1	4.5	5.6	6.8	8.0	9.1
2	2.0	2.6	3.0	3.8	4.5	5.4	6.0	7.5	9.1	10.6	12.0
2½	2.46	3.2	3.8	4.8	5.7	6.8	7.6	9.4	11.4	13.3	15.2
3	3.0	3.9	4.5	5.7	6.8	8.2	9.1	11.4	13.7	16.0	18.2
4	4.0	5.1	6.0	7.6	9.1	11.0	12.0	15.2	18.2	21.2	24.1

These ratings are based on 165 deg arc of contact and are not corrected for the action of centrifugal force. For light singles $\frac{1}{8}$ in. thick figure 90 per cent of these ratings. For heavy singles $\frac{3}{16}$ in. thick figure 112 per cent of these ratings.

DOUBLES:

Light: in. thick, 65 lb allowable effective tension per inch width
Medium: $\frac{5}{16}$ in. thick, 70 lb allowable effective tension per inch width
Heavy: $\frac{3}{8}$ in. thick, 80 lb allowable effective tension per inch width

Table 14-6. Horsepower Rating of Medium Double Mineral-retanned Belting $\frac{5}{16}$ In. Thick, Based on 70 Lb Effective Tension

Belt width, in	Belt speed, fpm

These ratings are based on 165 deg arc of contact and are not corrected for the action of centrifugal force. For heavy triple, 9/16 in. thick, figure 108 per cent of these ratings.

Combination of Oak-tanned and Mineral-retanned Leather Belting. This type is made of a combination of oak-tanned and mineral-retanned leathers. It is fabricated flesh side to flesh side and is available in doubles only. By this construction the high frictional grip of the mineral-retanned leather and the tough rigidity of the oak-tanned leather are combined into one belt. The combination of these features is desirable in heavy-powered slow-speed drives and particularly where the use of shifting belts for such driving is required.

It is specially manufactured for shifting drives and for stepped-cone and flanged-pulley operations, since the oak ply resists the transverse crumpling action caused by shifter forks, the edges of stepped cones, and pulley flanges.

Characteristics

1. Made in thicknesses and widths similar to medium and heavy double-oak leather.
2. Fabricated with a cement insoluble in water, moisture, or steam.
3. More flexible than double-oak leather, based on the mineral-retanned ply.
4. Coefficient of friction, 0.60 to 0.87.
5. Can be made endless by manufacturer or at point of application.
6. Will resist water, moisture, steam, temperatures to 130°F, mineral oils, and cutting compounds.
7. Nonresistant to the corrosive acids or their mists and vapors.
8. Should not be dressed with the compounds used for regular double-oak leather.

Horsepower Tables for Combination Oak-tanned and Mineral-retanned Leather Belting

Medium: 5/16 in. thick, 70 lb allowable effective tension per inch width
Heavy: 3/8 in. thick, 80 lb allowable effective tension per inch width

NOTE: Use Table 14-6 for horsepower ratings of medium-weight, 5/16-in.-thick combination oak-tanned and mineral-retanned leather belting.

For heavy weight 3/8 in. thick, figure 114 per cent of the ratings given in Table 14-6.

Atmospheric Effects on Leather Belting. *Oak-tanned Nonwaterproof.* An atmosphere charged with steam, moisture, or at a temperature above 115°F causes separation of the laps and plies. An atmosphere charged with the mists or vapors of the corrosive acids attacks the leather.

Oak-tanned Waterproof. An atmosphere charged with steam or moisture or at a temperature of 115°F has no effect on the laps and plies. An atmosphere charged with the mists or vapors of the corrosive acids attacks regardless of the special dressing of the leather and the use of pyroxylin cement.

Mineral-retanned Waterproof. An atmosphere charged with steam, moisture, or a temperature to 140°F has no effect on the laps and plies of the leather. An atmosphere charged with the mists or vapors of the corrosive acids attacks this type of leather, but its action is slow.

Combination of Oak-tanned and Mineral-retanned Waterproof. This type is steam- and moistureproof and will resist a temperature of 140°F owing to a special dressing of the oak ply, the use of pyroxylin cement, and the mineral-retanned ply, but the oak ply deteriorates when exposed to the mists or vapors of the corrosive acids.

Leather-belt Dressing or Lubrication. The term "dressing" as applied to leather belting signifies the lubrication of the fibers of the leather. It does not mean creating a sticky surface. Leather belting of all types requires periodical dressing or lubrication, since the heat generated by frictional contact with the pulleys tends to dry out the currying ingredients. This results in the leather becoming dry and hard. The leather should be dressed with a compound containing the currying ingredients so that penetration and a relubrication of the fibrous structure result.

Leather-belting manufacturers supply dressing compounds which contain the currying materials employed in the manufacture of oak-tanned nonwaterproof and waterproof leather belting. Mineral-retanned leather requires a compound different from that required by oak-tanned leather. Such compounds can also be obtained from the respective manufacturers.

Under normal atmospheric and operating conditions leather belting should be dressed every two or three weeks. The most effective results are obtained by applying the lubricant to the outer surface or ply. This permits the material to work its way through the leather and therefore prevents a slippery driving surface on the belt and an accumulation or gumming of the lubricant on the pulley face. If the pulley-contact surface of the belt is very dry, a small amount of the lubricant can be applied to this surface with safety

Cheap and low-grade stick and semiliquid belt dressings which generally contain the ingredients shown in Table 14-8 should not be used on leather belting of any type:

Table 14-8

Stick type	Per cent	Semiliquid type	Per cent
Graphite	22	Tar	36
Rosin	27	Rape seed or cotton oil	54
Vegetable oil	44	Rosin	10
Paraffin	7		

Correct Dressings for Leather Belting. *Oak-tanned Nonwaterproof* Preferably, compounds supplied by leather-belting manufacturers. Commercial castor oil and neat's-foot oil (3 parts castor to 1 part neat's-foot).

Oak-tanned Waterproof Same as for oak-tanned nonwaterproof.

Mineral-retanned Waterproof. Compounds supplied by leather belting manufacturers only.

Combination Oak Tanned and Mineral Retanned. Compounds supplied by leather belting manufacturers only.

Standard Prices of Leather Belting. The price of leather belting is set at a standard of 24 cents per foot of single ply, 1 in. wide; double or two ply, 48 cents per foot, 1 in. wide. These list prices are subject to current trade discounts.

Rubber Belting

Rubber belting, generally known as "friction-surface rubber," is composed of two or more thicknesses, termed plies, of various weights of cotton duck, impregnated and frictioned with a tough slow-aging rubber compound.

The cotton duck is the element of tensile strength. Therefore the belt is graded to the weight and quality of the duck. For the average rubber belting the duck weight varies from 28 to 32 oz which, according to the United States trade standard, signifies that the actual scale weight of a piece of duck 36 by 42 in. when dry is 28 to 32 oz. The actual weight of the duck is not solely the strength factor because quality, weave, and length of the fiber have a decided effect. The average ultimate tensile strength of 32-oz duck 1 in wide is 440 lb. In calculating the strength of rubber belting, a factor of safety of 20 is employed. The tensile strength of the entire belt is approximately one-third less than the sum of the plies when taken separately.

Table 14-9. Minimum and Maximum Plies of Rubber Belting

Width of belt, in.	Minimum number of plies	Maximum number of plies	Width of belt, in.	Minimum number of plies	Maximum number of plies
2	3	4	16	5	8
3	3	4	18	5	8
4	3	5	20	5	8
5	4	5	22	5	8
6	4	6	24	5	8
8	4	6	26	6	8
10	4	6	30	6	10
12	4	6	36	6	10
14	5	8	42	6	10

Table 14-10. Proper Number of Plies for Regular 32-oz Duck Construction, Based on Pulley Diameter and Speed

Number of plies	Pulley diameters, in		
	Under 2,000 fpm	2,000 to 4,000 fpm	4,000 to 4,500 fpm
3	2	3	5
4	4	6	8
5	10	14	18
6	16	20	24
7	22	26	30
8	28	32	38
9	34	38	44
10	40	44	50

The friction or the grade of the rubber compound employed governs the degree of adhesive tendency between the duck plies and also the coefficient of friction of the belt. This grading is measured in pounds and is based on the quality of the rubber compound. Frictions used are 20, 22, 24, 26, and 28 lb This pound friction is determined by the resistance of the rubber compound to the weight required. If a 28-lb friction is desired, a 28-lb weight or pull is applied to a peeled-back ply of the belt 1 in. wide It must not separate longitudinally more than 1 in. per min. The duck and the friction are the grading characteristics of rubber belting as a 28-oz-28-lb friction belt.

The manufacture of the belt is a series of operations: (1) The duck is thoroughly inspected and dried; (2) it is impregnated and frictioned with the rubber compound—the rubber must be compounded so that the resultant material will be highly elastic tough, and capable of retaining these qualities throughout the transmission life of the belt—(3) the cutting or sizing of the impregnated and frictioned duck to the belt width required; (4) folding and placing the duck strips based on the thickness or number of plies required if of folded construction—if of raw-edge construction, folding is not employed—(5) vulcanizing; (6) inspecting, testing, measuring, talcing, and rolling

Organic accelerators, antioxidants, flex-resisting ingredients, and many other new compounding materials have been developed by the rubber industry. All these improvements have been applied to the bonding material used in rubber-fabric belts. As a result, the quality of the bond has been steadily improved.

Characteristics. *Regular Folded Type and Raw-edge Type*

1. Made in 2, 3, 4, 5, 6, 7, 8, 9, 10, and 12 plies.
2. Made in widths from 1 to 84 in.
3. Ultimate tensile strength of good quality 32-oz duck per in. width equals 440 lb; of 28-oz duck per in. width, 360 lb.
4. Moisture-, water-, and steamproof.
5. Heatproof to 130°F.
6. Will not resist corrosive acids or their mists and vapors.
7. Cannot be penetrated by any belt dressing.
8. Deteriorates when exposed to excessive mineral oil.
9. Average coefficient of friction, 0.35 to 0.45.
10. Can be made endless, preferably by manufacturer.

Horsepower Formula for Rubber Belting (Standard-weight Duck Type). The general expression for horsepower transmitted by a belt is as given for the various types of leather belting; but for belting made of plies of fabric, the effective tension or $(T_1 - T_2)$ is expressed in pounds per inch width per ply of thickness or "pounds per ply inch." Therefore, the formula for duck-ply belting is expressed as follows:

$$\text{Hp} = WNS(T_1 - T_2)/33{,}000$$

where W = width of belt, in.
N = number of plies
S = belt speed, fpm
T_1 = tight-side tension, lb per ply inch
T_2 = slack-side tension, lb per ply inch
$(T_1 - T_2)$ = effective tension, lb per ply inch

Rubber-belt manufacturers have revised and simplified the formula for horsepower capacity in terms of maximum tension T_1. The simplified formula is

$$\text{Hp} = [WNS(T_1 - T_c)/33{,}000]\,[1 - (1/R)]$$

where Hp = hp capacity of belt
W = width, in.
N = number of plies
S = belt speed, fpm
T_1 = tight-side tension, lb per in. width
T_c = centrifugal tension per in. width
$[1 - (1/R)]$ = correction factor for arc of contact (see Table 14-11)

Thirty-two-ounce duck is generally used for good-quality rubber belting. Based on an average ultimate tensile strength for this weight of 440 lb, the allowable effective tension is 25 lb per in. width of duck or a factor of safety of 17½. $(T_1 - T_c)$ can therefore be calculated as 25 lb for a 32-oz duck belt and 20 lb for a 28-oz duck belt.

Initial Stretch of Ply-construction Rubber Belting. Friction-surface ply-constructed rubber belting will stretch initially; therefore under normal operating conditions it should be adjusted occasionally during the early periods. When applying this type of belting, it should be cut short of the actual length necessary as follows:

Three-, four-, and five-ply thickness, cut short $\frac{5}{32}$ in. per foot;
Six-, seven-, and eight-ply thickness, cut short $\frac{1}{8}$ in. per foot;
Nine-, ten-, and twelve-ply thickness, cut short $\frac{3}{32}$ in. per foot.

Table 14-11

Arc of contact, deg	$1 - (1/R)$	Arc of contact, deg	$1 - (1/R)$
90	0 29	190	0 51
100	0 32	200	0 53
110	0 35	210	0 55
120	0 37	220	0 57
130	0 39	230	0 58
140	0 41	240	0 60
150	0 44	250	0 61
160	0 46	260	0 63
170	0 48	270	0 64
180	0 50		

Atmospheric Effects on Rubber Belting. An atmosphere charged with moisture, water, steam, or a temperature of 120°F has no effect.

An atmosphere charged with mists or vapors of sulfuric and nitric acids deteriorates and finally destroys the outer or surface cotton-duck plies.

At temperatures above 120°F the rubber compound tends to dry out and crack.

When exposed to nitric acid the rubber compound becomes slimy, and the cotton disintegrates.

Continuous exposure to mineral oil causes deterioration of the rubber compound

Dressing the Rubber Belt. A rubber belt of any type cannot be penetrated by dressing compounds; therefore it is not possible to lubricate the internal fibers. All compounds applied remain on the surface of the belt; hence caution must be used in the compounds employed. Ply separation and loss of power-transmitting ability are frequently caused by the use of sticky, resinous dressings owing to the belt sticking to the pulley and the accumulation of lumps on the pulley face.

Rubber belting of all types should be dressed periodically with vegetable, castor, or linseed oils. These will remove the rubber "bloom" from new belting and soften the surface of used belting. These oils furnish a nondangerous tackiness or adhesiveness between the belt and the pulleys.

Stitched Cotton-duck Impregnated Belting

Cotton-duck impregnated belting is commonly known as "stitched canvas." It is composed of plies of impregnated cotton duck stitched or sewed together The quality of the belt depends upon the grade and weight of duck, the method of stitching, and the impregnating compound.

FIG. 14-4. Stitched cotton-duck belt—round-edge construction.

Construction. Generally, 36- to 37½-oz duck is employed for stitched cotton duck impregnated belting, having an ultimate tensile strength of 550 to 600 lb per in. width. The duck is cut and folded to the required belting size and stitched firmly together. The structure is impregnated with compounds to furnish durability, lubrication, and frictional value. After impregnation the excess compounds are removed, and the belting lengths are tensioned.

Types. There are two general types, the "round-edge" and the "folded edge" The round-edge construction, shown in section for four-ply and six-ply belting by Fig. 14-4, employs the "interlocked" stitch, particularly above four ply, in addition to the straight-through stitch; while the folded-edge construction, shown in section by Fig. 14-5 for four ply and six ply, employs the straight-through stitch for all thicknesses. The round-edge construction, in view of the interlocked stitch, results in a securely bonded belt and therefore furnishes resistance to ply separation. The round edge resists to a considerable degree the action of shifter forks and also tends to prevent premature cracking of the belt edge.

Table 14-12. Relation of Number of Plies to Pulley Diameters and Speeds

Belt speed, fpm	Pulley diameter, in				
	4 ply	5 ply	6 ply	8 ply	10 ply
Up to 1,000	3	4	6	12	24
1,000–2,000	4	5	8	15	30
2,000–3,000	5	6	10	18	36
3,000–4,000	6	7	12	21	42
Over 4,000	7	8	14	24	48

Characteristics

1. Made in 3, 4, 5, 6, 8, 10, and 12 plies.
2. Made in widths from 2 to 72 in.
3. Coefficient of friction, 0.25 to 0.60.
4. Possesses flexibility, elasticity, and resistance to ply separation.
5. Will hold any type of metallic fastener and can be rawhide or wire laced.
6. Should not be made endless.

Fig. 14-5. Stitched cotton-duck belt—folded-edge construction.

7. Resistance to moisture, water, steam, heat, and slight mineral oil.
8. Should not be used in the presence of the corrosive acids or their mists and vapors.
9. Actual acid contact quickly attacks the duck. Caustic stiffens the entire structure.
10. Temperature up to 140°F has no effect on the better grades of this type of belt. Above 140°F a drying out of the impregnating compound occurs.

Table 14-13. Horsepower Ratings of Good-grade, Stitched-cotton Duck, Impregnated Belting

Belt speed, fpm	Horsepower transmitted by a belt 1 in. wide				
	4 ply	5 ply	6 ply	8 ply	10 ply

This table, based on an arc of contact of 165 deg is corrected for centrifugal force.

Dressing the Stitched-cotton Duck Belt. The impregnating compounds of good-quality stitched-cotton duck belting serve as a lubricant to the cotton fibers during the life of the belt. When the belt is used in the proper atmospheric conditions, a tacky frictional surface is evident. Other forms of dressings are not required. The pulley surface of the belt should be periodically brushed, particularly when abrasive substances are present.

Camel's-hair Belting

Camel's-hair belting is composed of hair and cotton woven tightly together. It is known as "camel's-hair" belting because the principal power-transmitting medium is the long hair of Bactrian camels. The camel's hair and cotton yarns are woven together under heavy tension, resulting in a solidly woven one-piece fabric. After weaving the fabric is thoroughly impregnated with suitable compounds for the purpose of lubrication and protection.

Characteristics

1. Made in four thicknesses: lightweight, $^3/_{16}$ in. thick; single weight, $^1/_4$ in. thick; double weight, $^9/_{32}$ to $^3/_8$ in. thick, extra-heavy weight, $^9/_{16}$ in. thick.
2. Made in widths from 1 to 41 in.
3. Possesses high elastic qualities and flexibility
4. Remains soft and pliable during entire life.
5. Does not shrink.
6. Ability to absorb shocks.
7. Not affected by mineral oil, unless excessive
8. Moisture-, water-, and steamproof
9. Will resist temperatures up to 300°F
10. Will resist the action of the corrosive acid mists and vapors for long periods but stiffens under the action of caustic

Table 14-14. Relation of Thickness to Pulley Diameters and Speeds

Weight of hair belting	Thickness, in	Minimum pulley diameters, in	
		Up to 2 000 fpm	2 000 to 4 500 fpm
Light	$^3/_{16}$	3	5
Single	$^1/_4$	5	7
Double	$^9/_{32}$ to $^3/_8$	10	14
Extra heavy	$^9/_{16}$	16	24

Table 14-15. Allowable Effective Tensions of Camel's-hair Belting, Pounds per Inch Width

Weight	Thickness, in	Pounds
Light	$^3/_{16}$	40
Single	$^1/_4$	50
Double	$^9/_{32}$ to $^3/_8$	75
Extra heavy	$^9/_{16}$	100

Horsepower Formula and Table. Camel's-hair belting is solid woven, hence the horsepower capacities are based on definite allowable effective tensions per inch of width. The formula is similar to that used for leather belting.

Elastic Qualities. Because of the hair construction, camel's-hair belting possesses considerable elasticity. It should therefore be applied to the pulleys extremely tightly. Because of its high elastic qualities, initial stretch is immediately evident. This comes out rapidly. After one or two take-ups the belt will not stretch beyond its elastic limit.

Dressing the Camel's-hair Belt. The impregnating compounds used preserve and lubricate the structure. The heat of transmission and excessive oil gradually lessen the impregnating compound, therefore this lubricant and preserver should be replaced. Camel's-hair belting should be dressed periodically by special oils or dressings furnished by the manufacturers. No other dressings should be used.

Table 14-16. Table of Horsepower for Camel's-hair Double Belting

Speed, fpm	Width of belt, in.											
	3	4	5	6	8	10	12	14	16	18	20	24

3,500	20	27	34	41	57	73	87	102	117	132	146	175
4,000	23	31	39	46	65	83	100	116	133	150	166	200
4,500	26	35	44	52	73	93	112	131	150	169	187	225

For light or single, multiply ratings given by 0.55, for light-double, multiply ratings given by 0.75; for extra-heavy, multiply ratings given by 1.33 This table is conservative for average conditions; it is based on an arc of contact of 165 deg and is not corrected for centrifugal force

Solid-woven Impregnated Cotton Belting

Solid-woven impregnated cotton belting is made from long-fiber fine-quality domestic cotton woven solidly together to form various thicknesses of belting fabric. To protect the cotton from mechanical and atmospheric effects it is impregnated thoroughly with special compounds.

Table 14-17. Relation of Thickness to Pulley Diameters and Speeds

Thickness	Minimum pulley diameters, in.	
	Up to 2,000 fpm	2,000 to 5,000 fpm
Single	4	6
Heavy single	6	8
Double	8	10
Triple	15	18

Characteristics

1. Made in single, heavy single, double, and triple thicknesses.
2. Made in widths from 1 to 36 in.
3. Alternate wet and dry conditions cause stretch and shrinkage.
4. Ability to absorb shocks.
5. Not affected by mineral oil, unless excessive.
6. Moisture-, water-, and steamproof.

Horsepower Formula and Table. This type of cotton belting is a solid-woven product; therefore the horsepower capacities are based on definite allowable effective tensions per inch of width. The formula is similar to that used for leather belting.

Dressing the Solid-woven Cotton Belt. A solid-woven cotton belt is dressed by the impregnating compounds. They protect and lubricate the cotton fibers. Contact with mineral oil and the heat of transmitting power gradually reduce the compound. It should be replaced by special dressings furnished by the manufacturer. No other dressings should be used.

Table 14-18. Allowable Effective Tensions, Pounds per Inch Width

Weight	*Pounds*
Single	40
Double, up to 8 in	80
Double, 8 in and over	100
Triple	120

Balata Belting

Balata belting is constructed from 36- to 38-oz cotton duck, thoroughly impregnated with a gum called "balata." The gum resembles gutta-percha. The proper-

Based on an arc of contact of 165 deg and not corrected for centrifugal force Horsepower capacities for the various allowable effective tensions can be proportioned to this tabulation.

ties that distinguish it from other gums and make it especially valuable as a substance for power belting are its toughness and waterproof qualities. Balata gum will not bond with any foreign material. It will bond with balata only.

Table 14-20. Relation of Number of Plies to Pulley Diameters and Speeds

Number of plies	Minimum pulley diameters, in.		
	Up to 2 000 fpm	2,000 to 4,000 fpm	4,000 to 5,000 fpm
3	3	4	5
4	5	6	8
5	8	10	12
6	12	14	16
8	18	20	24
10	30	34	38

Characteristics of Balata Belting

1. Made in 3, 4, 5, 6, 7, 8, 9, and 10 plies.
2. Made in widths from 1 to 72 in.
3. Possesses low stretch.
4. The duck is impregnated with the gum, not frictioned.
5 Will resist water, moisture, and steam
6 Is dry-heat-proof to 105°F.
7. Balata gum melts at 120°F.
8. Low resistance to the action of mineral oil.
9. Can be made endless by manufacturer.

Dressing the Balata Belt. This type cannot be penetrated by any dressing compound. If the pulling surface becomes dry and hard, vegetable castor oil should be applied sparingly. This oil has a softening effect and produces a "tacky" nondangerous surface on the belt.

Teon Belting[1]

Teon belting is of cotton-duck ply construction. The plies are held together by a special cement reinforced by metallic brads arranged in longitudinal rows at close pitch. This metallic stitching aids in preventing ply separation.

---

[1] English manufacture.

Based on an arc of contact of 165 deg and not corrected for centrifugal force. Ratings based on 38-oz duck. For 36-oz duck, figure 92 per cent of ratings given.

Characteristics of Teon Belting

1. Made in light or three ply, medium, or four ply, heavy or six ply, and extra heavy or eight ply.
2. Widths: light, 1 to 4 in.; medium, 1 to 20 in.; heavy, 3 to 26 in.
3. Resistance to ply separation.
4. Can be made endless by manufacturer.
5. Will resist water, moisture, and steam.
6. Will resist heat to 300°F.
7. Will resist the action of the mists and vapors of the corrosive acids.
8. Will not resist caustic.
9. Will not resist bromic acid.
10. Possesses resistance to mineral oil.

Dressing the Teon Belt. This type cannot be penetrated by any dressing compounds. If the pulley surface becomes dry or glazed, vegetable castor oil or an oil supplied by the manufacturer should be applied sparingly.

Balata	No	Yes, slight	Yes	Yes	No	No	Yes	Yes
Teon	No	Yes	Yes	Yes	Yes	Yes	No	Yes

MAINTENANCE OF POWER BELTING

1. Belting when employed serves as a connecting medium between power source and application. It is equal in importance to the operating machines and the power plant. Production depends upon it.

2. Systematic care and attention are given to the power-source and production machines. Similar care and attention to power belting are absolutely necessary if efficiency of operation and maximum production are to be maintained.

3. The cost of repairs to a belt may be small, but the enforced idleness of men and the production loss based on such repairs are expensive. The value of a machine as a producer exceeds the wages paid the men who operate it. A slipping belt can cause heavy expense through loss of applied power.

4. Consideration of belting should begin with the design and installation of the transmission system. Belting of the proper type should be chosen for the atmospheric and mechanical condition involved. It should be of the proper type and size to transmit its load. A belt larger than necessary will more than repay in increased life and lessened maintenance expense the additional cost over a smaller overloaded belt.

5. Properly installed belting requires little attention, provided it is given regular and systematic care. Neglect and abuse are generally responsible for belting difficulties.

6. Belting maintenance should be centralized. One man should be held responsible. The man designated should make periodical inspections of all belt drives so that breakages, slip, and other difficulties may be anticipated and therefore avoided.

7. Belting should be maintained in proper physical condition so that it can transmit its capacity load without slip.

8. Belting requires dressing or lubricating; therefore it is important that the dressings be of suitable character to accomplish the results desired. Such dressings should be capable of relieving the internal friction of fiber on fiber, mellowing the belt and keeping it pliable, and furnishing a cohesive but not sticky grip on the pulleys.

9 Power is wasted in tearing a sticky belt free from the pulleys, and such tearing action is destructive to the belt.

10 When in proper condition, a belt will grip the pulleys with a clinging suction action and will release without adhesion. When so maintained the belt will carry its load without high initial tension. High tension has no value or purpose other than to eliminate slip.

11 Belting lubricating must be considered from the standpoint of the two general classes of belting. One class, such as leather, stitched canvas, solid-woven cotton, and camel's hair, consists of a porous structure which will absorb lubricants; while the other class, such as rubber, balata, and teon, are impervious to the absorption of lubricants. The dressings or lubricants for both classes of belting can be the same, but the method of application must be different. Belting having absorbing qualities should be treated sparingly at regular intervals both front and back. Approximately 60 per cent should be through the back. Belting of the nonabsorbent class should be given surface treatment only. This treatment should be very light and applied only as required to maintain a good friction and prevent polishing and glazing.

12 Belting of the nonabsorbing class is subject to cracks and pinholes. When operating in dampness, moisture will enter, become trapped, and will eventually rot the cotton duck. A proper surface dressing will prevent the entrance of moisture.

ESSENTIALS FOR EFFICIENT BELTING SERVICE

1 Pulleys should be slightly wider than the belt that they are to carry. This will prevent the belt's running over the rim and striking adjacent objects. The pulley should not have a sharp or too much crown.

2. Belting joints should be carefully made. The belt ends should be absolutely squared, so that the belt can run true and not stretch unevenly. Heavy lacing, which results in "bunches" at the joints, and oversized metallic fasteners cause loss of pulley contact, breaking of the belt at the joint, stiffness, and thumping of the belt against the pulley. A projecting fastener striking an obstruction or a badly adjusted shifter fork will cause rapid destruction of any belt.

3. Pulleys and shafting should be kept in perfect alignment. Much belting is ruined by neglect of this particular factor.

4. The laps of leather belting should be inspected frequently. As soon as the points of the laps show signs of lifting, they should be immediately cemented down.

5. Any defects developing at the joints should receive prompt attention. If lacings, hooks, or plates have damaged the ends of the belt, immediate attention should be given; otherwise the belt will give way and a shutdown result.

6. Belting should be kept clean. A coating of dirt will destroy its gripping quality. Dirt working into a belt is similar to sand in a bearing. It causes frictional heat which destroys the belting fibers.

7. Leather, stitched canvas, solid-woven cotton, and camel's-hair belting can be washed with a mixture of two parts gasoline to one of turpentine to loosen the dirt and then scraped with a dull knife. After drying, the proper lubricant or dressing must be applied.

8. Rubber, balata, and teon belting should be washed with soap and water only. After washing they should be carefully scraped and the proper surface dressings applied.

9. An oil-soaked leather belt should be immersed in the gasoline and turpentine cleaning mixture as above and allowed to soak for several hours. After drying, the proper lubricant or dressings should be applied.

10. Continuous stretch signifies that the belt is not strong enough for the load. A wider belt should be used. If this is not possible, use a thicker one, provided the thickness conforms to pulley diameter and speeds.

11. Any belt when overloaded and slipping is likely to slide off the pulleys. A belt will slide off a crowned pulley more easily than from a flat pulley. The remedy is to stop the belt's slipping by cleaning, dressing, tightening, or providing a wider or thicker belt.

12. If a belt is uniform with joint square and the pulleys are true and in line, it will not tend to work to one side of the pulleys on a horizontal shaft.

If a belt which is not overloaded is causing trouble by working to one side of the pulley, first make sure that the shafts and pulleys are perfectly in line. If the defects still persist when perfect alignment is obtained, the belt can be made to move to the desired side by drawing the shafts together on that side.

FASTENING OF POWER BELTING

Joining a power-transmission belt in an improper and careless manner results in high belting-maintenance costs, short belting life, and production loss.

Belt-joining Fundamentals

1. The belt should not be strained at the joint.
2. The fastener should not cut or weaken the belt.
3. The fastener should conform to the curvature of the pulley.
4. The fastener should resist wear caused by pulley contact.
5. The correct size and type of fastener should be used for pulley diameters and speeds.
6. The fastener should not prevent the belt being square and close fitting at the joint.
7. If metallic, the minimum amount of metal should be at the joint.
8. The fastener should be quick of application.

General Methods of Belt Joining

1. Endless
2. Laced
3. Metallic

The Endless Method

The endless method is the most efficient belt-joining method, since the joint is integral with the belt. Initial stretch is evident in all types of belting; therefor center adjusting facilities should be provided when this method is employed. Th leather belt offers the greatest possibility for the endless method because it is a multiple of cemented joints.

Making the Leather Belt Endless. *Regular Oak Nonwaterproof.* Scarf or scrape the ends down to a thin edge 3, 4, or 6 in. back, depending upon the width and thickness of the belt, and apply the hot glue to the two scarfed surfaces. Place the glued surfaces together and subject to continuous pressure for at least $2\frac{1}{2}$ hr.

Waterproof Oak, Mineral Retanned, and Combination Tannage. Scarf or scrape the ends down to a thin edge as described above and size the two scarfed surfaces first with a waterproof pyroxylin cement; allow this to dry. Apply another coating of the cement to the sized surfaces, place them together, and subject them to continuous pressure for at least 6 hr.

Uses of the Endless Belt

1. On motor drives when the motor is provided with slide rails
2. On pivoted motor drives
3. On motor drives, automatic-idler-pulley controlled
4. On high-speed spindle operations of machine tools when idler pulley control or center adjustment is possible
5. On adjustable mule-pulley drives
6. On large-powered engine drives

Directions for the Use of Regular Nonwaterproof Leather Belt Cement. Place the can in hot water and heat it. Thin to the consistency of thick syrup, and apply while hot in a thin coat, well rubbed in with a brush. Put the surfaces together quickly before the cement chills, rub the outside of the joint with a block of wood, and tap lightly with a hammer. *Have the cement hot, but do not allow it to boil.*

Directions for the Use of Waterproof Leather Belt Cement. *Caution: Keep this cement away from flames or cigarettes, etc.* Before applying cement, any grease or oil should be removed with gasoline or carbon tetrachloride, and all the old cement must be cleaned off. After preparing the splice, make sure that the laps are absolutely of even thickness in order to obtain a smoothly running belt. Roughen the surface with card cloth if available. Apply two coats of cement, using a brush, letting each dry 15 to 30 min before applying the next. After applying the third coat, immediately clamp the splice between boards with C clamps and let it stay 6 hr. Hammering the laps down instead of clamping is not acceptable.

The Laced Method

The laced method of joining belting employs rawhide or wire and is applicable to all types of belting.

Rawhide lacing is applied manually and results in an efficient and strong joint. The time required for application must be considered based on other equally efficient methods available. Rawhide lacing should always be employed on hand-shifted belting. It cannot injure the hands.

Wire lacing is applied either by machine or by hand and results in an efficient, strong, and flexible joint. There are two machine methods: one actually sews the ends of the belt together, while the other forms wire loops through which a pin of either rawhide or fiber is inserted.

Metallic Fasteners

Wire Hook with Rawhide or Fiber Pin. *Characteristics*

1. Easy to apply by either portable or stationary machine.
2. Results in an accurate and flexible joint.
3. Proper-size selection gives minimum amount of metal at joint.
4. Pressed into ends of belt so as to form a series of loops.
5. Loops are meshed together, and either rawhide or fiber pin is inserted.
6. Hooks are furnished on cards.
7. Hooks are of plain steel, stainless steel, bronze, or monel metal.

Pressed Steel, Hinged. *Characteristics*

1. Manual application.
2. No special machine or tools required.
3. Applied with a hammer.
4. Results in a strong and accurate joint.
5. Furnished in strips with jaws open.

Table 14-25. Minimum Pulley Diameters and Belt Thicknesses for Wire Hooks*

Standard hook size	Belt type and thickness	Minimum pulley diameter, in.
2	2-ply fabric and light single leather	2–3
3	3-ply fabric and medium single leather	3–4
4	4-ply fabric, heavy single and light double leather	4–5
5	5-ply fabric, light and medium double leather	6–8
6	6-ply fabric and heavy double leather	8–12

Table 14-26. Minimum Pulley Diameters and Belt Thicknesses for the Pressed-steel Hinge-pin Fastener*

Manufacturers' size	Belt type and thickness	Minimum pulley diameter, in.	Standard length of lacing, in.
20	3-ply fabric	3–5	12
L-27	4-ply fabric and heavy single-oak leather	6–7	12
M-35	5-ply fabric and light double-oak leather	8–11	8
U-45	6-ply fabric and medium and heavy double-oak leather	12–14	12
X-65	7- and 8-ply rubber, cotton, or balata	14 16	12

* Courtesy of the Alligator Belt Lacer Co.

6. Grips belt from both sides without weakening the leather or fabric.
7. Two hinge pins employed, designed to furnish rolling action at joint.

Bolted-plate Fastener. *Characteristics*

1. Manual application.
2. Punch, hammer, and wrench required.
3. Light canvas or leather between belt and plates recommended.
4. Specially designed bolts and nuts used for securing plates to belt.
5. Results in a strong and efficient joint.
6. Plates are designed to conform to curvature of pulley.
7. Pulley-surface washer designed to embed itself in belt.
8. When applied correctly, washer does not come in contact with pulley face.
9. Screw the bolt nuts tight.

Table 14-27. Plate Size, Based on Belt Width

Size of plate	Belt width, in.	Diameter of bolt, in.
0	1½–2	7/32
1 small	2½–4	¼
1 large	5–6	9/32
2 small	7	5/16
3 small	10–16	⅜
3 large	17–20	13/32
4	21–24	7/16
5	Above 24	½

Steel-prong Hook. *Characteristics*

1. Manual application.
2. No special machine or tools required.
3. Applied with hammer.
4. Results in strong and efficient joint.
5. Prongs bend flush with pulley side of belt.
6. Belt must be against hard surface when hook is driven through.
7. Is quick of application.

Riveted Steel-plate Fasteners. *Characteristics*

1. Manual application.
2. No special machine or tools required.
3. Plates secured to belt by specially designed rivets.

Table 14-28. Plate Sizes and Number to Use for Transmission, Conveyor, and Elevator Belting*

Belt width in	Light high-speed work	Light work	General work		Heavy work	Extremely heavy work
	2 in diameter of smaller pulley	3 in diameter of smaller pulley	6 in diameter of smaller pulley	9 in diameter of smaller pulley	12 in. diameter of smaller pulley	24-in diameter of smaller pulley
	High-speed plates	Short grip plates	Medium grip plates	Special-grip plates	Long-grip plates	Jumbo plates
½	One 20					
¾	One 20					Used also on conveyor and elevator belts on pulleys smaller than 24 in where speed is not excessive

12				Four 103	Four 149	Four 1 611
14				Four 123	Four 1 409	Four 1 611
16		For belt widths wider than 24 in use sufficient plates of the same grip series to cover the width of the belt completely			Four 189	Four 2 211
18					Six 149	Six 1 611
20					Eight 109	Five 2 211
24					Six 189	Six 2 211

* Courtesy of the Crescent Belt Lacer Co

† Where smaller pulley is 4½ in diameter or larger use No 06, covers 1½ in of belt width

4 Easily applied by a hammer
5 Results in a strong and efficient joint
6 Combines strength with light weight
7 Distributes power strain evenly across belt
8 Rivets spread flush with pulley side of belt when driven through.
9 Belt can be joined without removal from pulley
10 Prongs of rivets easily penetrate leather or fabric belting
11 Plate is designed to conform to curvature of pulley (see Table 14-28)

Note The plate fastener owing to its construction forms a nonflexible joint therefore the plate used must conform to the curvature or circumference of the pulley If the plate does not conform, premature breakage of the belt will occur immediately back of the plate

POWER TRANSMISSION BY BELTING

Initial Tension. Initial tension is measured in pounds per inch width and maintains the contact between pulley and belt necessary to pull the load with a minimum of slip with given friction properties of belt and pulley This tension must be increased as the power load increases, as the friction coefficient is reduced by foreign substances, as the stretch in the belt produced by the load and centrifugal

force loosens the belt on the pulley, and as the arc of contact decreases by high ratios, or where a stiff or thick belt operates at high speed over a small-diameter pulley.

Effective tension, signified in belting formula as ($T_1 - T_2$), is also an important factor in belting engineering. Figure 14-6 illustrates a belt weighted at each end and hung over a pulley. When the weights T_1 and T_2 are equal, the pulley will not revolve. This is equivalent to a power-transmission belt at rest. When the weight T_1 is heavier than the weight T_2, the pulley will revolve in the direction shown by the arrow. This is equivalent to a belt transmitting power. It is the difference in the weight of T_1 and T_2 which measures the turning force or torque applied to the pulley. This weight or tension difference is the effective power tension.

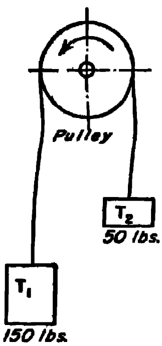

Fig. 14-6.

Computation of T_1 and T_2. To obtain the values for tight side T_1, slack side T_2, and total initial tension for a given load and speed, assume a 25-hp belt drive with a belt speed of 3,000 fpm, drive horizontal.

$$\text{Belt-power pull} = \frac{(25\text{ hp} \times 33{,}000\text{ lb})}{3{,}000\text{ fpm}} = 275\text{ lb}$$

The belt-power pull, or in this case 275 lb, is not the tight-side or T_1 tension because the coefficient of friction of the belt and the arc of contact have an influence.

To obtain the tight-side tension T_1, the power pull must be multiplied by a factor based on the coefficient of friction and the arc of contact given in Table 14-29. These values are based on oak-tanned leather on cast-iron pulleys.

Table 14-29. Tension Factors

Arc of contact, deg Smaller pulley	130	140	150	160	170	180	190	200	210	220	230
Horizontal drive	2.00	1.90	1.80	1.70	1.65	1.60	1.55	1.50	1.47	1.44	1.40
Vertical drive	2.10	2.00	1.90	1.80	1.75	1.70	1.65	1.60	1.57	1.54	1.50

In the above example assume the arc of contact on the smaller pulley to be 160 deg; then

$$T_1 = 275 \times 1.70 = 467\text{ lb}$$
$$T_2 = 467 - 275 = 192\text{ lb}$$

$$\text{Total static or initial tension} = 467 + 192 = 659\text{ lb}$$

Note: The preceding tension factors in Table 14-29 are calculated on a basis of approximately 0.31 coefficient of friction, which is a fair average for a good oak-leather belt on two moderately large cast-iron pulleys. If the pulleys were small and both of similar diameter resulting in 180 deg arc of contact, the horsepower capacity of the belt would be somewhat reduced. Inversely, if the two pulleys were of large diameter, it would be increased. Composition pulleys, such as paper, fiber, or leather, will increase the pulling power of the belt about 10 per cent. The nature of the drive itself can influence greatly the ability of the belt to pull the load. If the load is jerky and highly fluctuating, the total pulling capacity of the belt is proportionally less than for drives where the load is constant and steady. For these reasons a factor of safety should be used over theoretical calculations, and the determination of such a factor, which may vary from 25 to 100 per cent, is a matter of judgment.

Arc of Contact. This is an important factor, since the more wrap or contact a belt has on the driving pulley, the more power it will transmit. Regardless of the fact that 165 deg is generally assumed as a fair average for industrial driving and that belting-horsepower tables are calculated on this basis, the arc of contact must be considered where accurate calculations are necessary. The greater the arc of contact, the lower the belt tension and belt size. The horsepower ratings given in Tables 14-2 to 14-7 are suitable for the average driving, but where accuracy is necessary they should be corrected as follows:

The factor *R* is found by dividing the diameter difference of the pulleys in inches by their center distance in feet. By referring to the curve chart, Fig. 14-7, and with the factor *R* found, the arc of contact in degrees on the smaller pulley can be determined. With the arc determined, the correction factor for the table ratings can be found in Table 14-30.

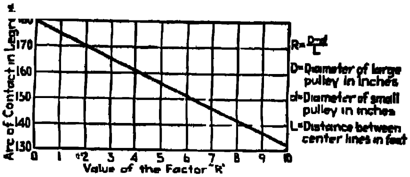

FIG. 14-7. Arc-factor curve chart.

EXAMPLE: Assume the arc of contact from the curve chart (Fig. 14-7) to be 130 deg; then the arc factor from Table 14-30, based on an arc rating of 130 deg would be 0.85. Assume 8 in. medium double-oak leather belt at 3,000 fpm. From Table 14-3 a belt of this character at this speed will transmit 47 hp at 165 deg arc of contact. On an arc of contact of 130 deg, it will transmit 47 × 0.85, or 39.9 hp.

Coefficient of Friction. All belting fundamentally transmits power by frictional contact between the belt and the pulley. This value varies with the types of belting and pulleys employed.

Table 14-30

Arc of contact, deg	Arc factor	Arc of contact, deg	Arc factor
120	0.81	170	1.02
125	0.83	175	1.03
130	0.85	180	1.05
135	0.87	185	1.07
140	0.90	190	1.09
145	0.92	195	1.10
150	0.94	200	1.12
155	0.96	205	1.13
160	0.98	210	1.15
165	1.00	215	1.17

Centrifugal Tension on Belting. Each particle of a belt as it moves in a curved path around a pulley exerts a centrifugal force which acts straight away from the center of the pulley. These forces combine to create a tension which is felt throughout the length of the belt. It is termed "centrifugal tension" and is in addition to any other existing belt tension. A diagram illustrating the action of centrifugal tension on a horizontal drive is shown by Fig. 14-8.

This action stretches and subjects the belt to a tension which lifts it away from the pulleys and therefore decreases its tractive grip upon them. On heavy belting at high speeds the centrifugal tension may equal the effective tension with the result that power transmission is negligible.

Formula for Centrifugal Tension:

$$T = \frac{W \times S^2}{116,000}$$

where T = centrifugal tension
W = weight of belt, lb per ft
S = speed of belt, fpm

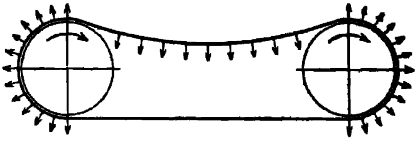

FIG. 14-8. Effect of centrifugal tension.

NOTE: Centrifugal tension is governed by the square of the speed. Doubling the speed increases it four times, and tripling it increases it nine times. Therefore very high-speed belts act at a disadvantage. Since the centrifugal tension is also governed by the weight of the belt, it is evident that, where high belt speeds are unavoidable, it is important to use the lightest weight belt that will do the work.

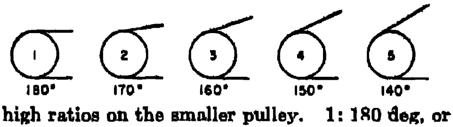

FIG. 14-9. Effect of high ratios on the smaller pulley. 1: 180 deg, or 100 per cent power rating on this arc. 2: 170 deg, or 4 per cent off power rating of 180 deg. 3: 160 deg, or 8 per cent off power rating of 180 deg. 4: 150 deg, or 13 per cent off power rating of 180 deg. 5: 140 deg, or 17 per cent off power rating of 180 deg.

Table 14-31. Horsepower Losses Due to Centrifugal Tension

Speed of belt, fpm	*Percentage of rated horsepower*
1,000	1
2,000	4
3,000	8
4,000	15
5,000	23
6,000	34
7,000	46
8,000	60
9,000	76
10,000	95

NOTE: These losses are applicable to belting running without automatic idler or pivoted motor base control.

	5-1	28
150-200	2-1	26
	3-1	28
	4-1	30
	5-1	32

NOTE: These center distances are based on actual experience. The figures should be employed on belted motor drives and all manner of belting installations where reasonable pulley diameters are used. Belt drives from engine flywheels and powers above 300 hp by belting are now exceptional; therefore for such service operating conditions must be considered.

Driving Ratios. The relation of the diameter of the driving pulley to the diameter of the driven one controls the speed ratio and the arc of contact of the belt on the driving pulley or the smaller pulley of the two. Without the use of an idler pulley a ratio of 1:1 furnishes a maximum arc of contact of 180 deg on open drives and relatively more on a crossed-belt drive. For efficient service a ratio of 6:1 should not be exceeded. Figure 14-9 illustrates the effect of various ratios on the arc of contact of the belt on the small pulley.

Center Distance. Belt drives without the use of automatic idler or pivoted-base motor control should have center distance proportioned to the pulley ratios, speed, and load requirements Short centers necessitate high-tensioned or "tight" belting, resulting in hot bearings, belt slippage, short belting life, and loss of power (see Table 14-32).

Vertical Drives. A belt operating vertically without center adjustment or idler control is a source of high maintenance and power loss. The stretch of the belting substance causes the belt to drop away from the bottom pulley. If a vertical drive is necessary and take-up facilities are not possible, the center distance should be comparatively short, based on the least amount of accumulated stretch per foot. Adjustable centers should be used, or a controllable idler pulley placed against the loose side of the belt, or a vertical-type pivoted motor base used. An angle of 15 deg from the vertical will help to eliminate vertical-drive difficulties.

Crossed-belt Drives. Crossed belting is used to reverse the direction of rotation and to increase the arc of contact. It is practicable, but the following factors must be considered:

1. **The ratio of a crossed drive should not exceed 4:1.**
2. **The cross should occur as close to the center between the pulleys as possible.**
3. **The width of the belting should not exceed 8 in.**
4. **The fastener must not interfere at the point of crossing.**
5. **Extremely short center drives should not be crossed.**

Quarter-turn Drives. A quarter-turn belt drive is employed to transmit power at right angles in a vertical, horizontal, or angular direction. It is a source of trouble and should not be used unless absolutely necessary. For best results a leather belt specially constructed for quarter-turn driving should be used. The quarter-turn drive should be installed correctly.

Rule for Installing Quarter-turn Drives. The center of the face of the loose side of the driver must line with the center of the face of the tight side of the driven.

Alignment of Shafting and Pulleys. In belt driving of any character, misaligned shafting and pulleys cause loss of power, high maintenance, and short belting life. Initially an installation may be in perfect alignment. During operation it should be checked periodically, based on the settling of foundations, expansion and contraction of woodwork, intermittent application of load, and machinery wear. Misalignment causes crooked-running belting and therefore slip, resulting in power loss and premature belt destruction, hot bearings, and excessive friction loads. The centers of the faces of the pulleys should be perfectly in line, and the shafting should be parallel.

Belt Slippage. Loss of power and belt destruction are primarily caused by belt slip. The following factors must be considered to avoid this action:

1. Type and thickness of belt not suitable for pulley diameter and speeds
2. Overload and underload
3. Insufficient initial belt tension
4. Dry, glazed, and hard belting; lack of proper dressing
5. Formation of lumps on pulley face by use of resinous dressings
6. Atmospheric effects
7. Misalignment
8. Improper joining

Shifting of Belting. Frequent or periodic sliding of a belt on tight and loose pulleys subjects it to edge wear and considerable transverse stress and crumpling action. Such strains and crumpling are more pronounced in wide belting regardless of thickness. To avoid such action, single leather and four-ply or equal-thickness fabric should not exceed 5 in. in width; and double leather or six-ply or equal-thickness fabric should not exceed a width of 8 in. when employed on shifting installations. Edge wear is primarily caused by wrongly adjusted and rough shifter forks. The fork should be smooth and straight and come in contact with the belt only when shifting. The roller-type shifter fork eliminates edge wear.

Pulley Diameters and Revolutions

Problem 1. Diameter and rpm of driver and diameter of driven known; to find rpm of driven.

Formula: $$\frac{\text{Diameter of driver} \times \text{rpm}}{\text{Diameter of driven}}$$

Problem 2. Diameter and rpm of driven and diameter of driver known; to find rpm of driver.

Formula: $$\frac{\text{Diameter of driven} \times \text{rpm}}{\text{Diameter of driver}}$$

Problem 3. Rpm of driver and diameter and rpm of driven known; to find diameter of driver.

Formula: $$\frac{\text{Diameter of driven} \times \text{rpm}}{\text{Rpm of driver}}$$

Problem 4. Rpm of driven and diameter and rpm of driver known; to find diameter of driven.

Formula: $$\frac{\text{Diameter of driver} \times \text{rpm}}{\text{Rpm of driven}}$$

Note: When pulley diameters result in fractions of an inch, the nearest whole number should be used.

FLAT-BELT PULLEYS

For efficient and economical power transmission by belting, the proper type and design of pulley should be used for the operating mechanical and atmospheric conditions.

Pulley Types. Six types of pulleys are available: paper, cast iron, fabricated steel, all wood, wood rim with cast-iron center, and metallic center with paper rim. Each type is manufactured in a number of designs to suit industrial requirements.

Pulley Essentials. The following factors should be considered when selecting type and design:

1. Frictional value of face surface.
2. Face must be smooth.
3. Ability to resist overload and shock.
4. Ability to conduct heat.
5. Solid or split design; split design facilitates installation and removal.
6. The pulley should be true in diameter.
7. Minimum air resistance.
8. Ability of material to resist steam, moisture, acid drip, and acid fumes.
9. Whether flywheel effect is required.
10. Should face be crowned or flat?
11. Do power and speed require a keyed or clamped pulley?
12. Interchangeability of bore.

Pulley Specifications. Pulley ordering will be facilitated by observance of the following:

1. *Service.* Specify character of service, horsepower requirements, and revolutions per minute.

2. *Description.* State whether solid, split, clamp hub or keyed, bushed or straight bored, tight or loose, flanged or special.

3. *Diameter.* Specify diameter in inches. This should be the first dimension given. If exact diameter is required, mention this and state whether measurements shall be made at crown or edge of rim. Unless otherwise specified, the diameter of a pulley is the diameter at the top of the crown.

4. *Face.* Specify face in inches. This should be second dimension given and should be in accordance with the width of the belt unless an exact width of face is desired. If exact face is required, the word "exact" must follow the face-width dimension.

5. *Bore.* Specify exact diameter of shaft in inches. This should be the third dimension given.

6. *Crown or Straight Face.* Specify whether crown or straight face. Crown face will be furnished if no specification is given. Drum pulleys for shifting belts have straight face. Tight and loose pairs have crowned faces.

7. *Key Seat or Setscrew.* Specify whether pulley is to be keyseated or setscrewed, or both.

Relation of Width of Pulley Face to Width of Belt. The face width of a pulley is determined by the required belt width. A pulley specification of 24 by 6 in. indicates a pulley having a crown-point diameter of 24 in. and sufficient face width to accommodate a 6-in.-wide belt. A 24- by 6-in. pulley will actually measure approximately 6½ in. width of face. This is standard practice for the purpose of securing full face belt contact. Up to and including 10-in. belt width, ⅜ to ½ in. wider pulley face is provided. From 12-in. belt width up, the pulley face is approximately 1 to 1½ in. wider than the belt.

Relative Speed Capacities of Pulley Types in Feet per Minute. *Cast-iron Type.* The cast-iron pulley is designed for rim speeds of 3,500 to 4,000 fpm. Rim speeds of 4,500 to 5,500 fpm are permissible and possible, but cast-iron pulleys to run at such speeds must be specially built and perfectly balanced. The cast-iron pulley can be employed for any practical power requirement.

Pressed-steel Type. Fabricated construction of the pressed-steel pulley permits with safety rim speeds of 4,000 to 5,000 fpm. This type, under test, has been operated at 14,000 fpm for 30-hr periods without failure. Such speeds, however, are not practicable for industrial driving. The pressed-steel pulley can be employed for any practical power requirements.

Wood Type. The all-wood pulley or the wood-rim pulley with cast-iron hubs and arms can be run with safety at rim speeds of 5,000 to 6,000 fpm. This type can be employed for any practical power requirement.

STEEL SHAFTING

Shafting is an important factor in mechanical power transmission. All methods employ shafting; therefore success or failure of the installation depends largely upon the proper selection of shaft size and the grade of steel employed.

Shafting for "group" power-transmission purposes, such as head-, line-, counter-, and jackshafting, is cold-finished, low-carbon steel of screwstock quality. Sizes up to about 2¾ in. are cold-drawn, while larger sizes are turned and polished. The physical properties of such steels vary and cannot be guaranteed; therefore the working stresses recommended are comparatively low. Shafting of large size or those requiring uniform physical properties are hot-rolled or forged and turned to finished size. The limits and methods vary by different manufacturers.

Cold-finished Steel Shafting. Shafting designated as "cold-finished" indicates the method of obtaining the finish and not the type of steel or its physical properties. To produce the shafting in sizes 2¾ in. diameter and under, the hot-rolled bars, after pickling for scale removal, are cold-drawn to size through tool-steel dies. The compression of the surface in cold drawing strengthens the steel to a certain depth. As the proportion of this strengthened surface to the total area increases, so will the tensile properties improve with decreasing size. When cold-finished steels are machined, thereby cutting the strengthened surface, the tensile increase is lost to a considerable extent. This tensile improvement is small on sizes from 2 to 2¾ in. in diameter. Shafting above 2¾ in. in diameter is usually turned and polished from hot-rolled bars, therefore the physical properties of such increased sizes are the same as for hot-rolled steel. The expression cold-finished may apply to alloy or straight-carbon steels as well as to screwstock. Specifications therefore should state not only the character of the finish but also the type of steel. Cold-finished medium-carbon and alloy steels are stronger than screwstock in the same proportion as hot-rolled medium-carbon and alloy steels are stronger than hot-rolled screw or machine steel (see Table 14-33 for physical properties).

Hot-rolled Steel Shafting. This type owes its superior strength to analysis and thermal treatment. Plain carbon steels such as SAE 1020, 1045, etc., become stronger in tensile strength with increasing carbon content. Above approximately 0.50 carbon, steels of this character are difficult to machine without annealing. Furthermore, if these steels are annealed, their strength is lower, and their cost is more than that of lower carbon steels or those of the medium-carbon, high-manganese type. This also applies to the alloy steels such as nickel, chrome nickel, chrome molybdenum, or chrome vanadium. Alloy steels such as these should never be employed in the annealed or untreated condition, since untreated alloy steels are more expensive, more difficult to machine, and their physical properties are no better than medium-carbon steels of the high-manganese type. Alloy steels when used should be quenched and drawn (see Table 14-34 for comparative physical properties of the hot-rolled steels).

A characteristic that is particularly applicable to hot-rolled and untreated steels whether carbon or alloy is that with increasing size, tensile strength and yield point drop with no increase in ductility. Therefore, when a size selection is being made, allowance should also be made for this fact. When physical properties of such steels are specified they should be made in connection with size from which test specimens are taken. When physical properties of heat-treated alloy steels are stated, they must be allied with definite sizes. For example, assume that a 5-in.-diameter shaft is desired with a tensile strength of 140,000 lb; the steel selected must possess the required tensile strength in 5 in. round and not as specified for ¾ or 1-in.-diameter stock-test specimens.

Tensile strength indicates the static strength of the steel. The amount of repeated stress endured without breakage (fatigue strength) is proportional to tensile strength. The shear resistance, torsional strength and hardness by Brinell, Rockwell, or Shore are also proportional to this property. Hardness tests by any of the foregoing methods have not provèd reliable as an index for the two important qualities of machinability and abrasion resistance. These qualities are apparently dependent on structure rather than hardness.

Alloy Steels. Alloy steels should always be heat-treated, either before or after machining. For transmission shafting it is not practicable to heat-treat after machining; therefore when alloy steel is necessary for this service, the preheated type should be employed. An attribute of the alloy steels is that they can be hardened after machining; thus they are adaptable for parts requiring a greater surface hardness than can be machined. For all purposes, with the exception of carbonizing, the alloy steels should be of 0.30 to 0.55 carbon content, since such a carbon content enables them to respond properly to heat-treatment. In these steels carbon content usually increases with size.

Yield point indicates the actual working limit of the steel and is the figure to employ when determining shaft size or section required to resist a given load or stress It is usually considered comparable to compressive strength and therefore is particularly adaptable for calculations of high-pressure or shock-resisting parts such as gearing, machine shafting, and sprockets.

Elongation and Reduction. Elongation and reduction are measures of ductility, shock resistance, and ability to stand sudden overload. If these figures are low, the steel may be termed "brittle."

Modulus of elasticity indicates the degree of deflection under a given load. The modulus 29,000,000 to 31,000,000 psi is essentially the same for any kind or condition of steel. Soft machine steel possesses a modulus similar to that of heat-treated alloy steel; therefore the latter with identical cross section will deflect to the same extent with similar loading This factor is of great importance in the design of transmission shafting to carry heavy loads in combination with belt or chain pull between bearings The deflection capacity of the shaft must be based on diameter and not on the use of steels having high tensile strength.

Table 14-33. Physical Properties of Cold-finished Steel Shafting, SAE Numbers

Type	Tensile strength, psi	Yield point, psi	Elongation in 2 in., per cent	Reduction of area, per cent	Size diameter in.
Hot-rolled soft steel or screwstock	50/60,000	30/35 000	20/30	35/45	1–2
Cold-finished screwstock, SAE 1112 or 1120	70/100,000	55/90,000	10/20	32/41	Up to 1
Cold-finished screwstock, SAE 1112 or 1120	50/60,000	30/40,000	20/35	35/45	2¾–4
Cold-finished, 35/45 carbon, SAE 1040	70/90,000	35/50,000	20/30	35/50	1½–2
Cold-finished annealed, 35/45 carbon alloy such as SAE 3140, 2340, 6140, etc	90/110,000	60/70,000	20/30	55/65	Up to 1½

Shaft Failures. Transmission shafting usually fails from abnormal deflection, torsional fatigue, or progressive fracture. The usual term applied is "crystallization." This term is a misnomer because all steel is crystalline, and the structure is not changed by breakage. Breakages result in a crystalline appearance of a portion of the fracture, while other portions of the fracture have been smoothed or rubbed down by abrasion or wear of the parted contacting surfaces prior to complete rupture.

Table 14-34. Physical Properties of Hot-rolled Steel Shafting, SAE Numbers

Type	Tensile strength, psi	Yield point, psi	Elongation in 2 in., per cent	Reduction of area, per cent	Brinell hardness	diameter, in.
Soft steel, SAE 1020	50/60,000	30/35,000	20/30	35/45	150/200	1–2
Medium carbon, SAE 1045	80/90,000	45/50,000	15/26	32/42	170/210	1–2
Medium carbon, high, manganese SAE X1340	90/110,000	55/60,000	20/30	35/45	163/207	1–2
Machinable (annealed) alloy, SAE 3145, 2345, 6145	80/100,000	50/60,000	25/35	30/40	180/220	1–2
Machinable heat-treated alloy, SAE 6150	140/150,000	120/130,000	14/20	52/60	302/340	1¾–3
Machinable heat-treated alloy, SAE 6150	145/160,000	120/135,000	15/20	42/52	302/340	3–6

Shafting failures can be minimized by the proper filleting of cross-section changes, keyways, etc., and by particular attention to torsional resistance and deflection capacity. These factors are more important as the strength of the steel employed increases.

Shaft-size Determination, Primary Factors

Service:

1. Source of power and kind of driven machines
2. Normal and maximum power to be transmitted
3. Steady or fluctuating load
4. Magnitude and duration of shock loads
5. Revolutions per minute and direction of rotation
6. Center distance and relative elevation of driver and driven

Kind of Drive:

1. Flat or V belt, rope, chain, gears, friction, or direct-connected by coupling or clutch to reduction gear or motor
2. Size and type of belt or ropes

Pulleys, Sprockets, or Gears:

1. Size and weight
2. Number of arms, length and location of hubs
3. Location on shaft in relation to bearings

Bearings:

1. Rigid or self-aligning, roller, ball, or sleeve type
2. Type of lubrication
3. Length of bearing surface on shaft
4. Method of supporting bearings

In heavy or important installations an approximate shaft weight should be included in first calculation and checked when shaft size is definitely determined. All stress factors acting upon the shaft should be considered, such as weight of shaft, belt, chain attachment, material carried, and any unusual erection or operating condition. Shaft sizes are generally large when speeds are low, when bending loads are heavy, or when bearings are not close to the bending loads. Smaller shafting can often be used with safety and economy by increased speeds and by proper mounting of the shaft in antifriction bearings. Shafts that are too small can be relieved of excessive stress by an additional bearing or by relocating bearings in relation to loads.

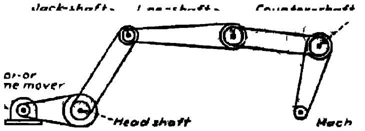

FIG. 14-10. Identification of group method of shafting.

Shafting for Group Method. Cold-finished shafting is usually employed. Power requirements are comparatively low, and shaft speeds in rpm are such that high stresses are not involved. In view of this, empirical formulas by Thurston have been arranged for quickly solving shafting problems of this character.

Identification of "Group-method" Shafting. Figure 14-10 indicates the name and location of the various shafts employed in the group system of driving by belting, chain, or a combination of these mediums.

Note. This arrangement is not necessarily standard for the group method, since in many cases the motor is directly belted or chain connected to the line shaft. The line shaft is then known as the "head line shaft." The jackshaft is used for ratio purposes and also to break up long center distances. Frequently the use of a countershaft is unnecessary, the machines being direct belted or chain connected from the line shaft.

Head Shafts. *Location.* First shaft from motor or prime mover.

Service. Reduces speed between motor and line or jackshaft and must have load capacity for entire installation.

Stresses. Torsional and bending.

Supports. Usually two bearings of the rigid type on adjustable base plates. The shaft is short, based on the usual provision for one power-receiving pulley, sprocket, or sheave from the motor and one power-delivery pulley or sprocket from the head shaft. Three bearings may be used, but for the average head shaft this is the maximum.

Speeds. Industrial range 25 to 550 rpm.

Formula:

$$\mathrm{Hp} = D^3R/125$$
$$D = \sqrt[3]{(125 \times \mathrm{Hp})/R}$$

where Hp = horsepower
D = shaft diameter
R = rpm
125 = constant for a combined torsional and bending safe-working stress of 2,800 psi

Note: Use constant of 125 only when head shaft is subjected to heavy strains, such as slow speeds and intermittent loads, or where clutches, shifters, or gearing are necessary. For the average head-shaft installation use 110 as the constant.

Line Shafts. *Location.* Can be first shaft from motor or first or second shaft from head shaft.

Service. Acts as a power-distributing shaft to the various pieces of apparatus or machines of the group.

Stresses. Torsional and bending.

Supports. Usually three or more bearings, spacing depending upon power pulls by belt or chain and the dead load of pulleys, gears, sprockets, sheaves, clutches, and couplings. Self-aligning adjustable bearings should be employed wherever possible. If the rigid type of bearing is necessary, provide adjustable base plates.

Speeds. Industrial range 70 to 400 rpm.

Formula. For line shafts 75 to 100 ft long, heavily loaded, and bearings spaced on 8-ft. centers

$$\mathrm{Hp} = D^3R/100$$
$$D = \sqrt[3]{(100 \times \mathrm{Hp})/R}$$

where Hp = horsepower
D = shaft diameter
R = rpm
100 = constant for a combined torsional and bending safe-working stress of 3,200 psi

Note: For line shafts 50 to 75 ft long, medium loaded, with bearings spaced on 8-ft centers, use constant of 90. For line shafts 20 to 50 ft long, lightly loaded, with bearings spaced on 6-ft centers, use constant of 75.

Jackshafts. *Location.* Either between head and line shafts, or between line and countershafts.

Service. For the increase or decrease of velocity ratio or to reduce center distance between principal shafts.

Stress. Torsional and bending.

Supports. If short, two or three bearings of either the rigid or the self-aligning adjustable type; if long, three or more bearings of the self-aligning adjustable type.

Speeds. Industrial range 100 to 400 rpm.

Formula. Same as for line shafting, with similar constants based on loading.

Countershafts. *Location.* Usually employed between line shaft and driven apparatus or machine.

Service. For increase or decrease of velocity ratio to machine or as a power-input control medium to driven machine.

Stresses. Torsional and bending.

Supports. Two or three bearings of either the rigid or the self-aligning adjustable type. When used as a component part of the driven machine, two bearings are usually employed.

Speeds. Industrial range, 100 to 600 rpm

Formula. For average service and loading

$$\mathrm{Hp} = D^3R/80$$

$$D = \sqrt[3]{(80 \times \mathrm{Hp})/R}$$

where Hp = horsepower
D = shaft diameter
R = rpm
80 = constant for combined torsional and bending safe-working stress of 3,600 psi

Specification Numbers for SAE Steels. A numeral index system is used for the specification of SAE steels, which facilitates the specifying of these steels on drawings and in the field. Such numerals are partially descriptive of the quality of material covered by these numbers. The first numeral of the number indicates the class to which the steel belongs; thus the numeral 1 indicates a carbon steel, 2 a nickel steel, and 3 a nickel-chromium steel. In the case of the alloy steels the second numeral of the number generally indicates the approximate percentage of the predominant alloying element. Usually the last two or three numerals of the number indicate the average carbon content in "points" or hundredths of 1 per cent. Thus 2340 indicates a nickel steel of approximately 3 per cent nickel (3.25 to 3.75) and 0.40 per cent carbon (0.35 to 0.45), and 71360 indicates a tungsten steel of about 13 per cent tungsten (12 to 15) and 0.60 per cent carbon (0.50 to 0.70). The basic numerals for the various qualities of steels specified are shown in Table 14-35.

Table 14-35

Steel	*Basic numeral*
Carbon	1
Nickel	2
Nickel-chromium	3
Molybdenum	4
Chromium	5
Chromium-vanadium	6
Tungsten	7
Silicomanganese	9

STEEL-CABLE TRANSMISSION BELTING

BY PAUL SULOFF

Mechanical Goods Design Staff, The Goodyear Tire & Rubber Company

Steel-cable transmission belting is assembled with a single or double helix of steel cable embedded in rubber or synthetic compound and encased in one or more envelopes, usually of cotton fabric, which give lateral strength to the cable helix and protect it from abrasion (see Fig. 14-11). The cable itself is ordinarily 0.035 to 0.050 in. in over-all diameter, with individual wires 0.006 to 0.008 in. in diameter. The ultimate strength of the wire is usually on the order of 300,000 to 350,000 psi, and the strength of the cable, 200 to 350 lb. Assembled into the belt, this results in belt strength on the order of 4,000 to 6,000 lb per in. of width, with final elongation of 1.5 to 2.0 per cent. The belt thickness may be from $\frac{3}{32}$ to $\frac{3}{8}$ in., depending on its width and the number and weight of envelopes required by the dictates of lateral strength and good proportion.

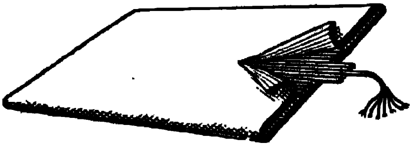

FIG. 14-11. Section of steel-cable transmission belting.

This type of belting has been designed to provide horsepower capacity per unit of width in excess of other types of belting. Because it can be kept extremely thin and free of internal bending stresses, its high ratings can be carried down into the small-pulley drives. Its extremely high elastic constant keeps the amount of take-up required to a minimum, and freedom from any hygroscopic effect on the length eliminates any shrinkage problems.

Generally, steel-cable belts are built endless by the manufacturer, but where necessary they can be vulcanized endless in the field. Standard metallic fasteners are not recommended since they will not hold at the ratings given this type of belt.

For horsepower ratings of steel-cable belting see Table 14-36.

Table 14-36. Maximum Horsepower Rating for Compass No. 250 Steel-cable Belts per Inch of Belt Width at 180 deg Arc of Contact to Be Applied against Peak Load

Small-pulley diam, in.	Belt speed, fpm																
	100	500	1,000	1,500	2,000	2,500	3,000	3,500	4,000	4,500	5,000	5,500	6,000	7,000	8,000	9,000	10,000
4	0.29	1.4	2.6	3.4	4.1	4.7	5.2	5.6	5.9	6.2	6.3	6.3	6.2	5.2	3.3		
5	0.35	1.6	2.9	4.0	4.8	5.7	6.5	7.2	7.8	8.4	8.8	9.1	9.0	8.2	6.6	3.8	
6	0.41	1.8	3.4	4.6	5.8	6.8	7.7	8.6	9.5	10.2	10.8	11.3	11.6	11.6	10.6	8.6	5.5
7	0.44	2.0	3.7	5.1	6.6	7.8	9.0	10.0	11.0	11.8	12.4	12.9	13.2	13.4	12.8	11.8	10.0
8	0.49	2.2	4.1	5.9	7.5	9.2	10.7	12.0	13.2	14.0	14.4	14.7	14.8	15.0	15.0	14.8	14.7
9	0.54	2.3	4.5	6.3	8.1	10.0	11.8	12.4	14.8	16.0	17.0	17.4	17.6	18.2	18.0	17.8	17.7
10	0.57	2.4	4.8	6.9	9.0	11.0	13.0	15.0	16.8	18.5	19.6	20.2	20.5	20.8	21.0	20.8	20.6
12	0.65	2.7	5.4	8.0	10.6	13.2	15.8	18.2	20.4	22.6	24.5	25.7	26.2	26.6	27.0	27.0	26.6
14	0.74	3.1	6.2	9.4	12.5	15.4	18.4	21.4	24.2	26.8	29.2	30.8	31.6	32.0	32.5	32.5	32.0
16 and over	0.86	3.6	7.2	10.8	14.3	17.8	21.2	24.5	27.8	30.7	33.5	35.7	36.6	37.1	37.5	37.6	37.2

These ratings reach values that are approximately twice the highest ratings given cotton-rubber cord belting.

Steel-cable belting requires no more and no less tension than other rubber-surfaced belting. It has the advantage that, because narrower belts can be used, the bending moment on the overhanging motor shaft is less, and bearing force is lower even though the belt tension is unchanged.

Crowns recommended for pulleys for steel-cable belts are given in Table 14-37.

Tests conducted on steel-cable belts for response to crown show that they respond to a given crown to much the same degree as cotton-rubber belts. In general, shaft misalignment in excess of 1 deg cannot be corrected for by crown.

The high elastic constant (low elongation) of the steel-cable belt, which is an advantage on ordinary open drives, prevents its use on most quarter-turn and twisted-belt drives, since the uneven distribution of strain across the belt width results in highly localized tensions destructive to the belt.

Table 14-37. Recommended Maximum Crown

(Difference between diameter at center and at edge)

Pulley-face width, in.	Large pulley, in.	Small pulley
2– 5	$\frac{1}{32}$	Flat–$\frac{1}{32}$ in.
6– 9	$\frac{3}{64}$	Flat–$\frac{1}{32}$ in.
10–15	$\frac{1}{16}$	Flat–$\frac{1}{32}$ in.
16–30	$\frac{3}{32}$	$\frac{1}{32}$ in.

While some extraordinary precautions must be taken to use successfully steel-cable belts, the high rating and length stability of this belt make it a power-transmission medium for many applications.

These same characteristics of high strength and rating coupled with length stability have been taken advantage of in designing steel-cable V belts.

The high elastic constant of steel-cable belting has also made possible the current development of positive-drive flat belting. In the past, efforts to design a positive-drive flat belt employing engaging teeth on belt and pulleys have been handicapped by the difficulty of maintaining pitch in the belt in the face of elastic and inelastic elongation. Steel cable has reduced these factors to an amount probably less than the pitch change resulting from wear in a chain.

Positive-drive steel-cable belts in widths from ¼ to 2 in. are being developed around the steel-cable flat-belt carcass to maintain a fixed ratio between shafts for loads up to 10 hp. These have teeth molded on the inner surface of the belt and engaging recesses machined in the pulleys. This type of belt offers a quiet lubrication-free method of maintaining a fixed speed relationship between shafts for light and moderate loads. At present, such drives are being custom designed for original equipment uses since expensive manufacturing equipment precludes the design of individual drives. Future design may include standard-pitch belts and pulleys for selection of drives for individual applications.

Steel-cable belting has been in successful operation for several years, and while other strong fibers are coming up to challenge the position of both steel and cotton, there is still nothing with the concentrated power capacity and length stability of steel.

MULTIPLE AND VARIABLE-SPEED V-BELT DRIVES

BY H. A. WILSON

Application Engineer, Texrope Drive Department, Allis-Chalmers Company

The V-belt drive consists of one or more endless belts of trapezoidal cross section, run on sheaves with V-shaped grooves on the periphery. The endless belts are constructed of cotton or rayon cords and fabric impregnated with rubber. V belts are also made with endless steel cables as tension members. Horsepower ratings for belts are given in Tables 14-39 to 14-43.

Table 14-38

Belt section	K	t	n	W	Kn	tn	Maximum sheave diam
A	0.213	0.020	22	0.07	4.686	0.440	5.0
B	0.225	0.034	37	0.12	8.325	1.258	7.0
C	0.241	0.061	72	0.19	17.350	4.393	12.0
D	0.250	0.106	149	0.39	37.250	15.790	17.0
E	0.250	0.160	227	0.59	56.750	36.320	28.0

V-belt drives are primarily short center drives and provide a smooth, even flow of power, with a minimum of slip and without noise. These drives can be operated in either direction with slack side of belts on top or bottom. They are especially adapted to reversing service.

OPERATION OF V-BELT DRIVES

Alignment of V-belt Drives. The driver and driven shafts should be parallel, and the belts should be at right angles to the shafts. Any appreciable misalignment may cause undue wear on the belts.

Adjustment of V-belt Drives for Proper Tension. Every installation of V-belt drives should include some form of movement to permit maintaining proper tension on the drive. This can be accomplished through the use of slide rails or a base on the motor or a pivoted motor base. An idler may be used where no other form of adjustment is possible. A grooved idler operating on the inside of the belts is to be preferred to a flat-face idler operation on the back of the belts. V belts (cotton or rayon) may stretch approximately 4 per cent of their original pitch length during their entire useful operating life. Provision should be made for this amount of take-up so that proper tension can be maintained at all times.

Replacement of V Belts. All tension should be removed from the drive and as much slack as possible obtained on the belts. The belts can then be removed easily and a complete new set placed on the drive. A complete new set of belts is recommended because of the difficulty of matching new belts with the old belts which have been used and have stretched an unknown amount. V belts should never be pried onto the sheave. A bar or any object used for this purpose may rupture the cord construction of the belt causing it to break.

Storage of Spare Sets of V Belts. Belts should be stored in a cool, dry place. Light, heat, and moisture will cause deterioration and greatly reduce the useful life of the belts.

Belt Dressing. No belt dressing of any kind should ever be used on any V-belt drive. The application of belt dressing will cause deterioration and shorten the useful life of the belts.

Table 14-39. Horsepower Ratings for A-section V Belts

Velocity, fpm	Sheave diam						
	2.6 in.	3.0 in.	3.4 in.	3.8 in.	4.2 in.	4.6 in.	5.0 in. and larger
1,000	0.5	0.7	0.8	0.9	0.9	1.0	1.0
1,100	0.6	0.7	0.9	1.0	1.0	1.1	1.1
1,200	0.6	0.8	1.0	1.0	1.1	1.2	1.2

SELECTING A V-BELT DRIVE

Selection of a V-belt drive for any application should be based on the nature of the load, the type of driving unit, horsepower (name-plate rating) and speed. To obtain the horsepower capacity to be used, multiply the rated horsepower of the driving unit by the recommended service factor for the type of driven unit (see Table 14-44). The belt section to be used for a drive is dependent on the rating and speed (see Table 14-46). Belt velocities should be under 5,000 fpm for maximum belt life. Sheave diameters used should not be less than recommended minimum diameters as shown in Table 14-47. Corrections for arc of contact on small sheave are determined by

Table 14-40. Horsepower Ratings for B-section V Belts

formula

$$\text{Arc of contact} = 180 - [(D - d)60]/C$$

where D = diameter of large sheave
d = diameter of small sheave
C = center distance of drive

See Table 14-48 for correction factors.

Center Distance. Knowing the sheave sizes required for a drive and the approximate center distance, the belt length can be estimated by the use of the formula

$$L = 2C + (\pi/2)(D + d)$$

Select the nearest belt length from Table 14-45 (page 1003).

5,000	5.2	7.6	9.5	11.0	12.2	13.2

The exact center distance can be calculated from formula

$$C = \frac{b + \sqrt{b^2 - 32(D - d)^2}}{16}$$

where $b = 4L - 6.28(D + d)$

L = pitch length of belt

For small ratios and long centers, reasonably accurate centers can be found by the formula

$$C = [L - 1.57(D + d)]/2$$

Table 14-42. Horsepower Ratings for D-section V Belts

5,000	12.5	15.7	18.3	20.6	22.6	24.4

The pitch length of the belt given in Table 14-45 is used in all calculations.

Example. A fan operating continuously at 420 rpm is to be driven by a 10-hp 1,750-rpm motor. Center distance between fan and motor shaft is approximately thirty-two inches

Solution: From Table 14-44 the overload factor for fans is 1.4 to 2.0 depending on the type of motor used. With a squirrel-cage motor the service factor will be 1.6 (heavy-duty fan) Horsepower of drive, therefore, is 1.6 × 10 = 16 hp Speed ratio 1,750/420 = 4.16 From Table 14-46 a B belt is recommended. Since B belts will be used, the minimum-size sheave recommended is 5.4 in. (see Table 14-47). The driven sheave required would be 22.46 which is not a stock size (See Table 14-58). Therefore, the sheaves which should be selected would be 6 and 25 in. which are stock sizes. Next determine the length of belt which will give nearest the center distance required. This length can be estimated by

Table 14-43. Horsepower Ratings for E-section V Belts

$L = 2C + (\pi/2)(D + d)$. In this case $L = 2(32) + (3.14/2)(25 + 6) = 112.8$. Therefore, a B112 belt should be used. Using the formula for center distance

$$C = \frac{b + \sqrt{b^2 - 32(D - d)^2}}{16}$$

the center distance will be found to be 31.2 in. A 6-in. sheave operating at 1,750 rpm will have a belt velocity of 2,745 fpm. From Table 14-40 the horsepower per belt will be found to be 3.6. Correcting horsepower for arc of contact on small sheave

$$\text{Arc of contact} = 180 - [(D - d)60]/C$$

From Table 14-48 correction is 0.90; 90 × 36 = 3.24. Finally (16/3.24) = 4.94. Therefore five belts will be required, and the drive will be 5-B112-60-250.

Horsepower Transmitted by V Belts. The following formula was developed for horsepower transmitted by V belts by Robert F. Vogt, former Chief Consulting Engineer for Allis-Chalmers Manufacturing Company

$$\text{Hp/belt} = \left[KT_0n - \frac{4Etn}{3N_id} - \frac{W}{g}\left(\frac{V}{60}\right)^2 \right] \frac{(T_1 - T_2)}{(T_1 - T_c)} \frac{V}{33{,}000}$$

where Hp/belt = horsepower recommended per belt
K = load safety factor
T_0 = breaking strength per cord
N = number of cords in belt
E = modulus of elasticity of cords
t = outer cord distance from neutral axis of cord section
N_i = number of cords per square inch
d = diameter of small sheave
W = weight of belt per foot of length
g = gravity constant
V = velocity of belt, fpm

T_1 = tension on tight side
T_2 = tension on slack side
T_c = tension due to centrifugal force
KT_0N = maximum allowable tension
$4Etn = T_b$ = bending-stress term
$\frac{W}{g}\left(\frac{V}{60}\right)^2 = T_c$ = centrifugal-force term

$$\frac{E}{N_t} = 190$$

$$T_0 = 14 \text{ lb}$$

$$\frac{(T_1 - T_2)}{(T_1 - T_c)} = \frac{R - 1}{R} = 8$$

where R = tension ratio = 5

The general horsepower formula can be converted to a more simplified form by using the constants given in Table 14-38 (page 996). The simplified formula is

$$\text{Hp/belt} = [0.339Kn - 6.141tn - 0.209WS^2]S$$

where $S = \frac{V}{1{,}000}$

When two cross sections are shown:
If sheave pitch diameters are limited, use the smaller cross section.
If sheave face widths are limited, use the larger cross section.
If no limitations, use cross section providing the most economic drive.

VARIABLE-SPEED V-BELT DRIVES

Variable speeds for V-belt drives can be obtained by the use of **variable-pitch-diameter sheaves.** Vari-Pitch variable-pitch-diameter sheaves for A-, B-, C-, D-, E-, Q-, and R-section belts are made. Two types of Vari-Pitch sheaves are available: **stationary control,** in which the adjustment for speed must be made with the drive stopped, and **motion control,** in which the adjustment for speed can be made with the drive running.

Table 14-53. Face Widths of Companion Sheaves

(Used with wide-range Vari-Pitch sheaves)

Size of Texrope belt	No. of grooves			
	1	2	3	4
Q section	1½ in.	3⅞ in.	6¼ in.	8⅝ in.
R section	....	4⅞ in.	7⅞ in.	10⅞ in.

Variable-speed drives using one Vari-Pitch sheave provide speed adjustments from 14 to 28 per cent for standard A-, B-, C-, D-, and E-section belts and 150 to 190 per cent for Q- and R-section belts. The use of two Vari-Pitch sheaves on a drive increases the variation proportionally, and the amount of variation depends on the sizes of sheaves used. Tables 14-61 to 14-64 show sizes of Vari-Pitch sheaves.

Companion sheaves are required for drives using Vari-Pitch sheaves owing to the construction of the sheave. The groove spacing of Vari-Pitch sheaves is not the same as for standard fixed-diameter V-belt sheaves. Table 14-65 (page 1025) gives face width of Companion sheaves.

Selecting a Vari-Pitch Drive. The data required for selecting a Vari-Pitch drive are the same as for a standard V-belt drive, and the rating is the same except when the drive is used for a constant horsepower application. In this case, the horsepower rating must be calculated using smallest pitch diameter.

Horsepower tables for Q and R belts are given in Table 14-51. Serial numbers and pitch lengths of Q and R belts are given in Table 14-52. Face widths of Companion sheaves for Q and R belts are given in Table 14-53.

V-FLAT DRIVES

A small grooved sheave used with a large flat pulley and a set of V belts are most successful when the following conditions are satisfied:

1. The speed ratio is 3:1 or more.
2. The center distance is less than the diameter of the large pulley. Centers of ¾ the diameter of the large pulley are desirable and should not exceed 1½ times the diameter of the large pulley.

10	6 3/8	8 7/8	12 1/16	16 1/2	20 1/8

3. The large pulley has a flat face (no crown).
4. The face width of the flat pulley is at least 1 in. wider than the face width of the grooved sheave. For large drives a 10 per cent increase in face width should be used.

Flat pulleys of cast iron or pressed steel are generally used. If crown-face pulleys are used, there will be unequal tension between the center and outer belts which may cause the belts to "crowd" toward the center of the crown.

Selecting a V-flat Drive. The correction factors for arc contact in Table 14-55 should be used. The pitch diameter of the flat pulley (for calculation purposes) is found by adding to the diameter of the flat pulley the amount shown in Table 14-56. All other data required are the same as for a V-belt drive.

QUARTER-TURN V-BELT DRIVE

Quarter-turn drives (Fig. 14-12) are used to transmit power from a horizontal shaft to a vertical shaft or vice versa. Speed ratios should not exceed 2½ to 1. Horsepower ratings of belts are 75 per cent of those listed in Tables 14-39 to 14-43. The arc of contact correction factor is disregarded. The center distance should not be less than $5(P + W)$ where P = pitch diameter of larger sheave, and W = face width of large sheave. The center line of the horizontal shaft should be half the diameter of the large sheave above the center line of the vertical shaft, and the vertical shaft should be offset half the diameter of the small sheave. Special deep-groove sheaves are required. Face widths of deep-groove sheaves are given in Table 14-57.

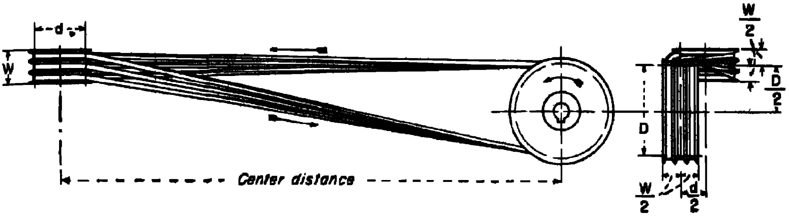

Fig. 14-12. Quarter-turn V-belt drive.

FLYWHEEL EFFECT (WR^2) OF V-BELT SHEAVES

In Fig. 14-13 the lines on the left, designated *B*, *C*, *D*, and *E* represent the standard sections of belts. To use the chart, find the place where the lines representing the pitch diameters of sheaves intersect the lines (WR^2 standard sheave) for the correct section of belt, and read on the right the value (WR^2) per inch of width. Multiply the face width of sheave in inches (Table 14-50) by the value read on chart, and the result will be the WR^2 of a standard sheave.

To find WR^2 for heavy flywheels where the value WR^2 is given, determine the WR^2 per inch by dividing the total WR^2 by the face width in inches, and read to left to intersect with diagonal line (pitch diameter) for size of sheave required. Then read at bottom of chart the extra weight to be added to a standard sheave (per inch of width). The total extra weight required to be added to a standard sheave will be found by multiplying the value read at bottom of Fig. 14-13 by the face width of sheave in inches.

"Magic-Grip" sheaves are of cast-iron construction and are made in two general types so far as location of hub is concerned. These two types are illustrated by Fig. 14-14. Tables 14-58 to 14-60 list the type in which each pitch diameter is furnished. In general sheaves up to 8.6 in. pitch diameter in B section, 10.6 in. pitch diameter in C section, and 18.0 in. in pitch diameter section are made in web style; larger sheaves have arm-style construction.

Note: The terms "Texrope," "Vari-Pitch" and "Magic-Grip" are trade-marks of Allis-Chalmers Manufacturing Company.

PIVOTED AND SPRING AUTOMATIC MOTOR-BASE DRIVES*

BY SAMUEL L. ALLEN

Design Engineer, J. E. Rhoads and Sons

The pivoted motor-base drive is a carefully engineered power-transmission unit adopted by industry for the efficient operation of short center belt drive installations. It utilizes the simplest form of power transmission: a motor, two pulleys, a strong flexible belt, and a pivoted motor base. The motor is mounted on adjustable base arms which are free to rotate about a horizontally mounted pivot shaft (Fig. 14-14*a*) or ball-and-socket bronze bearing (Fig. 14-14*b*).

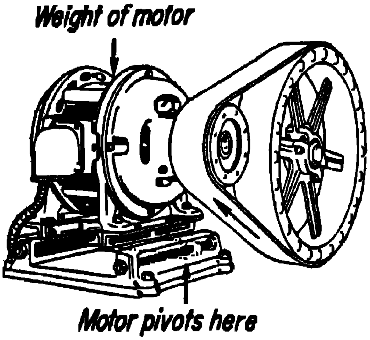

FIG. 14-14*a*. Motor mounted on pivoted motor base.

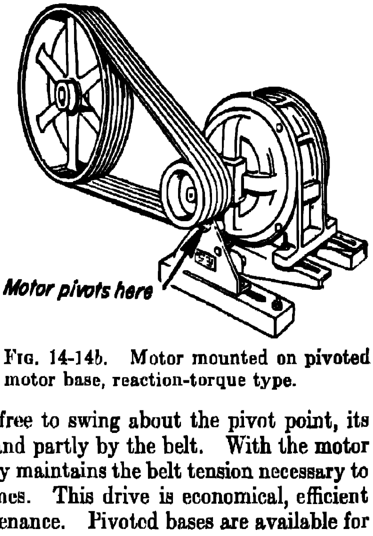

FIG. 14-14*b*. Motor mounted on pivoted motor base, reaction-torque type.

The motor is bolted to the arms and is free to swing about the pivot point, its weight being supported partly by the pivot and partly by the belt. With the motor correctly placed on the arms, it automatically maintains the belt tension necessary to ensure a continuous flow of power at all times. This drive is economical, efficient dependable, and requires little, if any, maintenance. Pivoted bases are available for practically every size of motor, and they can be installed to operate vertically, horizontally at any angle, mounted on the ceiling, on the floor, on the wall, or mounted on the machine itself.

Pivoted bases are adjustable devices which can be used on many types of installations almost too numerous to mention. Some of the more common uses are on fans, compressors, machine tools, pumps, generators, industrial line shafts, textile spinning frames, beaters, etc.

CLASSES OF BASES

There are two distinct classes of bases: One is the Rockwood base which depends mainly upon motor weight to supply tension to the belt, acting through an adjustable lever arm. The other is the American Econ-o-matic base with the pivot point close to the motor shaft. This base utilizes mainly the twisting or rotating action of the stator which is equal and opposite to the rotor action. The motor weight is offset enough to give initial tension, and the load determines the tension in the belt automatically. The underlying principles of these drives are the same, but motor weight is more important in one type than the other. These two bases, properly applied and designed, control belt tension accurately, making short center-belt drives practical and economical. These two general classes are suitable for floor, ceiling, wall, and vertical drives. Three special textile bases for spinning and twister frames are available for motors up to 20 hp at 1,800 rpm.

---

* The data and tables for this subsection are by the courtesy of J. E. Rhoads and Sons, American Pulley Co., Automatic Motor Base Co., and Rockwood Manufacturing Co.

Figure 14-15 shows the different types of Rockwood bases and their range of application.

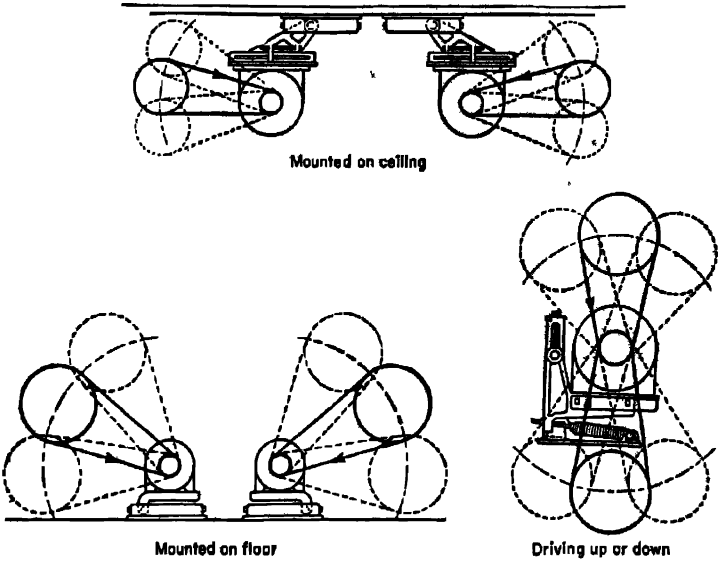

FIG. 14-15. Range of application for Rockwood bases.

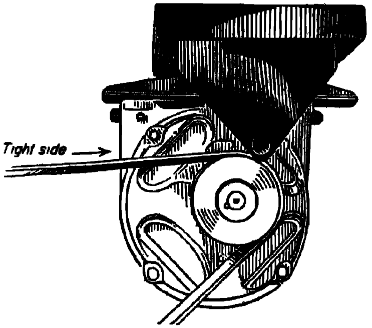

FIG. 14-16. Ceiling-drive type, American base.

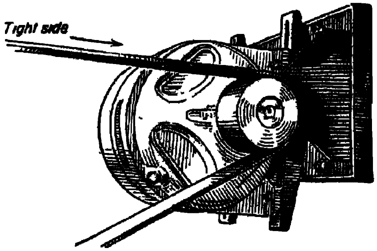

FIG. 14-17 Wall-drive type, American base.

Figures 14-16, 14-17, 14-18, 14-19, and 14-20 show the different types of American bases. On all drives, the tight side of the belt must be near the pivot. This rotation gives increased tension with increased load and decreased tension with decreased load. The opposite rotation gives just the reverse of this, and some drives may be inoperative. In this case, the drive should be changed or a different base used so that the load pull comes near the pivot.

Ceiling-type Bases. Frequently ceiling drives constitute a trouble zone for plant maintenance men. Belts stretch, but because of their inaccessibility, they are not given proper attention, and production is slowed down owing to excess slip. A pivoted motor base on the ceiling will correct this.

The floor-type American base is used on the ceiling with special emphasis on the belt direction. The tight side of the belt must approach the face of the motor pulley closest to the pivot of the base (see ceiling installation, Fig. 14-16).

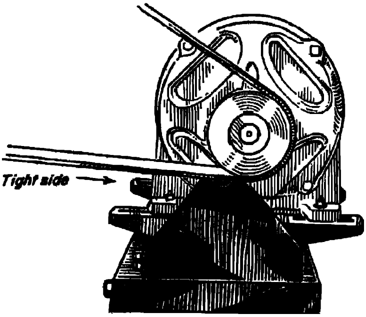

FIG. 14-18. Floor-drive type, American base.

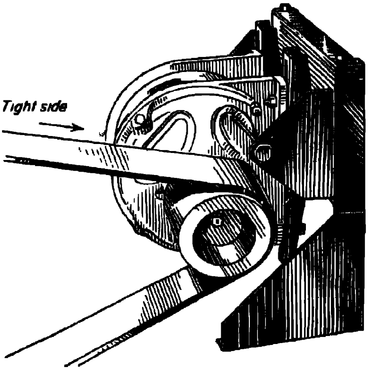

FIG. 14-19. Topside-drive type, American base.

The Rockwood base for use on ceiling drives has special hanger arms and auxiliary adjusting screws for changing tension, if necessary. All other adjustments are the same as in the floor base.

Vertical-type Bases. Fixed-center vertical-motor drives cause trouble sooner or later because of belt stretch resulting in slip and loss in production. The special vertical-type Rockwood base eliminates all this trouble. With the motor above, the springs support the entire motor weight and supply belt tension. With the motor below, the springs take off the motor weight not needed for belt tension.

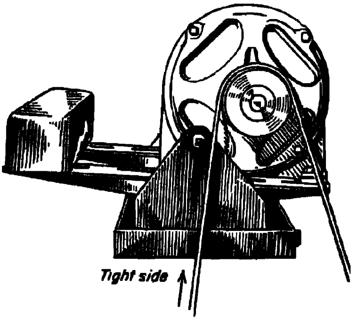

FIG. 14-20. Down-drive type, American base.

The American down-drive base (Fig. 14-20) mounted either on suitable brackets or platform keeps the belt tight with the motor above. The topside base (Fig. 14-19) is used when the center line of the drive is within 45 deg of the vertical. Both types have all the adjustable features found in the regular floor-type bases.

Construction of Rockwood Bases. On a standard base, the motor is bolted rigidly to a pair of steel arms instead of to the usual slide-rail motor base. These arms are pivoted on a steel shaft which is in turn mounted on adjustable screws running the length of the housing. Therefore, the entire pivot shaft can be moved forward or back to accommodate an endless belt length by turning the adjusting screws. The arms are movable parallel to the pivot shaft to accommodate different motor-frame sizes and for alignment. These arms are provided with slots on the sides so that the motor bolted to the arms can be moved toward the pivot for less tension or away from it for more tension, giving a wide range of belt tensions, the final position being determined by the load to be transmitted. The large take-up provided is sufficient in most cases to take care of speed changes by using pulleys of different diameter.

If the base is not quite parallel to the driven shaft after installation, the pivot shaft can in most cases be made parallel by turning one of the long adjusting screws. This can be done while the drive is running. Since the pivot shaft is below the motor feet, the end bells on the motor can be removed without removing the motor from the base. The many adjustments provide interchangeability of motors in case of failure or in many cases make it possible to install a larger motor on the same base without moving the base on its foundation. Figure 14-21*a* shows a typical pivoted motor-base flat-belt drive of the Rockwood floor-type base driving a fan.

Construction of the American Base. The American Econ-o-matic motor base is made of steel throughout—steel because it combines strength with lightness. Steel also has a natural elasticity which relieves and neutralizes any destructive forces that may be set up within the motor because of imperfect balance of the motor, pulleys, or belt. Resilient steel absorbs noise-producing vibrations and motor hum, thus taking the place of an expensive type of noiseproof foundation. The base itself is perfectly quiet in operation, the finished assembly permits no looseness or rattle.

The only moving part is the "cradle" made of cast- or forged-steel cranks, solid-steel cross rods, and pressed-steel motor-base arms. This cradle is pivoted in bronze bearings* of the ball-and-socket self-aligning type. These bearings ensure free movement in any position and eliminate all danger of "freezing" or "binding."

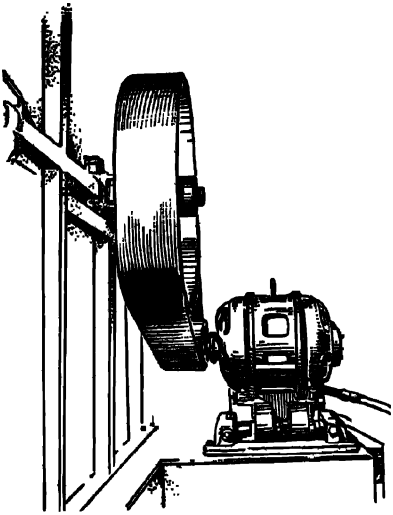

FIG. 14-21*a*. Typical floor-type Rockwood-base installation driving an air-conditioning fan.

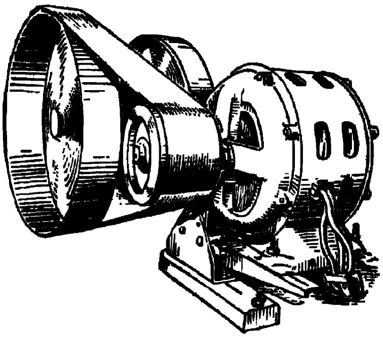

FIG. 14-21*b*. Floor-type American-base installation driving compressor.

Standard bases are available in seven sizes; duplex-type bases in nine sizes; topside bases in five sizes; and there is also a full line of textile bases for spinning and twisting frames. Other bases can be built to special dimensions when required.

It is a simple matter to adapt the base to motors of various dimensions. Liberal adjustments, easily accessible, have been provided in the foundation plates, in the bearing standards, and in the motor-base arms. Any adjustments necessary for the correction of belt alignment or for the take-up of belt stretch can be made while the drive is in operation.

Figure 14-21*b* shows a floor-type installation using a special-tannage leather belt on an American base driving a compressor.

BELT ELONGATION

Belt elongation occurs from centrifugal tension, too much tension, high humidity, heavy loads, too small a belt, and permanent stretch. Stretch allows the motor to tilt on these variable-center drives, but ring-oiling bearings leave a permissible tilt of −7 deg from the horizontal before the arms have to be leveled up by turning the screws provided. Ball-bearing motors can tilt any amount as long as the arms do not bottom on the base. For the sake of appearance, the feet should be kept horizontal.

---

* With the exception of A00 and A0.

THE BELT

While any type of belt can be used on the pivoted motor drive, certain belts are better than others. Special-tannage, endless leather belts are very flexible, have the highest grip on the pulleys, can be made endless any desired length, and on the average last longer. Cord belts, V belts, chrome-tanned leather belts, oak belts, special-tannage leather belts, rubber belts, steel-cable flat belts, and others have all been used successfully.

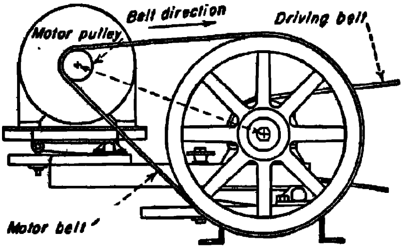

Fig. 14-21c. Double-reduction Rockwood-base drive.

Steel-cable V belts can be operated at 6,000 fpm or higher, but the manufacturer should be consulted on these drives.

The steel-cable flat transmission belts require special engineering, and the manufacturer should be consulted regarding these belts and pulley crowns. High-speed drives up to 10,000 fpm are possible with this steel-cable flat belt.

While any type of pulley can be used, the pulleys presenting the greatest resistance to slip should be used. The motor pulley should be paper or wood, and the driven pulley as well, when the pulley ratio is near unity. Large driven pulleys may be cast iron, pressed steel, or wood. V sheaves should be used with V-belt drives.

All pulleys selected should be large enough for the job to be done. Table 14-66 shows NEMA standard minimum motor-pulley diameters for a given motor size. Motor pulleys smaller than those recommended by NEMA introduce high belt tensions and bearing pressures; therefore, they should be avoided where possible. Belt speeds between 2,500 and 4,500 fpm are ideal. Speeds up to 6,000 fpm and higher are permissible under certain conditions but are not generally recommended. The exception is the steel-cable construction referred to above.

Pulley ratios up to 8:1 are permissible, and ratios up to 60:1 on the double-reduction gravity-base drive are practical, see Fig. 14-21c.

MOTOR FLOAT OR VIBRATION

With the motor free to follow the load pulsations, the motor must move in unison with these pulsations. The amount of vibration or motion depends upon several factors. If the load is steady, the float may hardly be noticeable. Drives on violently fluctuating loads may need snubbers to keep the drive steady. A base too small for the motor may cause vibration, resulting in breakage of some part of the base. Uneven belt thickness, eccentric pulley, and uneven load are all causes of motor vibration. Occasionally, a motor rotor may be out of balance causing undue vibration. With the motor free to follow the load pulsations, the motor, machine, and bearings are freed of these harmful load shocks, and longer machine, bearing, and belt life results.

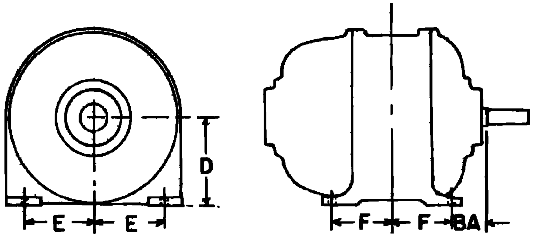
Pulley Centers

Pulley centers may be as short as the diameter of the large pulley, although preferably a little longer. Some drives have very short centers with the pulley faces just missing each other. These ultrashort centers are found mainly in the textile industry on spinning- and twister-frame drives where the space is very limited and the speed ratio is about 2.5:1 or less with a range of 5 to 20 hp. Large horsepower drives may require long centers depending upon circumstances. Most of these drives will come within 12 to 14 ft.

Efficiency

The efficiency of the pivoted drive varies somewhat with the belt, but it reaches a peak around 99 per cent which it closely approaches over a wide range in tensions. Pivoted drives should be designed to handle the maximum capacity of the motor, which for most types of motors is at least 150 to 250 per cent of their rated capacity. However, motors usually operate at less than their rated capacity, so that the drive is operating most of the time at less than one-half its peak capacity. This load characteristic makes important the ability of the drive to maintain its high efficiency under fractional load (see horsepower slip curves and horsepower efficiency, Fig. 14-22).

Table 14-66. Recommended Minimum Pulley Diameters for Pivoted Motor-base Drives



NEMA frame size	Min pulley diam, in.	Floor-base size, Rockwood	*D*	*E*	*F*	*BA*
203	3	0	5	4	2¾	3⅛
204	3	0	5	4	3¼	3⅛
224	4	0	5½	4½	3⅝	3½

504	12	12	12½	10	8	8½
505	15	12	12½	12½	9	8½

$F + BA + \frac{1}{2}$ pulley face width $= S$.
S = center of motor and base to center of motor pulley.

GRAPHICAL METHOD FOR DETERMINING PIVOT CENTER DISTANCE

Suggestions for Layout. Select the pulley diameters commensurate with the horsepower and load to be transmitted. Suggested minimum motor pulleys are shown in Table 14-66. Figure the driven pulley diameter D by the following method:

EXAMPLE:

Let
motor hp = 50
Motor rpm N = 860 full-load speed
Motor pulley diameter d = 14 in.
Fan rpm n = 167

Then

$$D = dN/n = (14 \times 860)/167 = 72\text{-in. diameter driven pulley}$$

If the fan speed must be figured more accurately, add the thickness of the belt to each pulley diameter, and deduct 1 per cent from the driven speed for slip and creep losses. Accurate pulley sizes can be figured by the same method; but add 1 per cent of driven speed to the speed wanted, and deduct the belt thickness from the pulley diameters.

Direction of Rotation. It is desirable on floor, wall, and ceiling drives to have the tight strand near the pivot shaft, although a few ceiling drives will operate better with the tight side away from the pivot. This can be controlled by the position of the motor as well as the direction of rotation of the driven shaft.

Center Distance. The center distance may be as short as the large pulley diameter (as long as the pulley faces do not touch) although preferably a little longer.

Slope of Center Line between Pulleys. The most favorable position of the motor is with its center on a level with the driven pulley center, although few drives have horizontal centers. The motor center is usually below the driven shaft, or it can be slightly above.

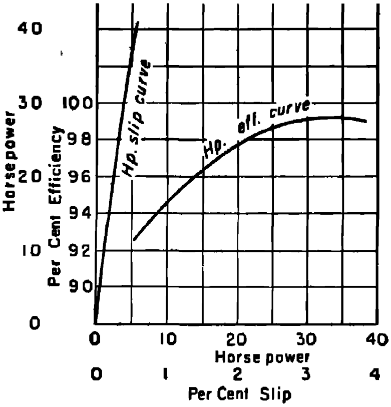

FIG. 14-22. Efficiency and slip chart.

Solution for Pivot Center Distance

Having selected the motor, pulley diameters, center distance, and position of the base to give the load pull near the pivot, the proper setting of the base can be determined. First, calculate the belt tensions at the peak load. The second step is to determine the offset of the motor needed to balance the resultant belt tension.

Nomenclature

In the following calculations, a slide rule can be used:

Initial Data:

D = diameter of driven pulley, in.
d = diameter of motor pulley, in.
C = distance between pulley centers, in.
H = height of center of driven pulley above the bottom of the Rockwood base, in.
P = peak load to be transmitted, hp[*]
N = speed of motor at peak load, rpm
n = speed of driven pulley, rpm
W = weight of motor, lb

Data to Be Determined:

V = belt speed, fpm
T_1 = tension in tight side of belt, lb
T_2 = tension in slack side of belt, lb
G = resultant belt tension, vector sum of T_1 and T_2, lb
$T_e = T_1 - T_2$ or effective tension, lb
e = pivot center distance (horizontal distance between motor center and pivot shaft, in.)
K = see Table 14-69
$\pi = 3.14$

Calculate:

$$V = d\pi N/12 \tag{1}$$

$$T_e = 33{,}000P/V \tag{2}$$

$$(D - d)/C \tag{3}$$

---

[*] Safe values of peak load for line-start motors may be taken as 2.5 times the name-plate rating; compensator-started motors as 1.5 times name-plate rating. These values for peak load may be adjusted according to the frequency of occurrence or the inertia and character of the load.

From Table 14-69, take the corresponding value of K for the type of belt and small pulley to be used.

$$(4) \qquad T_1 = T_e K \qquad T_2 = T_1 - T_e$$

Carry through the following operations:

1. From the motor-dimension sheet, select the appropriate base size or from Table 14-66, 14-67, 14-68 or 14-72. For motors not listed, consult your belting supplier.
2. Lay out the side view of the drive to any convenient scale. First, draw the floor, wall, or ceiling line on which the base is mounted. Then include any post, pipes, etc., which limit the location of the drive. Finally, place the pulleys in their positions to assure getting the correct angle of drive. Extend the lines of the belt strands to their point of intersection.*
3. From the point of intersection B, lay off T_1 to any convenient scale on the engineer's rule along the tight strand. At C, lay off T_2 parallel to the slack strand using same scale as above. Draw and scale the resultant belt tension $G = BG$.
4. Draw a vertical line through the center of the motor, and from its intersection A with the resultant belt tension, lay off G on its extension using the same scale as in (3) or to a smaller scale if more convenient. $AX = BG$, only a smaller scale is used.
5. At X, lay off the motor weight W vertically downward using the same scale as in (4). Draw the diagonal from W to A.
6. Draw a horizontal line at the level of the pivot. Its intersection Q with the diagonal AW locates the desired horizontal position of the pivot shaft. The horizontal position of the base with relation to the pivot shaft can be determined from the dimensions shown in Tables 14-71, 14-72, or 14-73. The work may be checked by measuring e and P. If correct, We equals GP. P is perpendicular distance from Q to the resultant BG.

Table 14-67. Rockwood-base Selection Tables

Base No.	Motor horsepower and rpm based on NEMA frame sizes			Heaviest motor for this base, lb	Shipping wt, lb
	1,800	1,200	900		
0	1	3/4	1/2	150	35
	2	1 1/2	1		
2	3	2	1 1/2	250	55
	5	3	2		
4	7 1/2	5	3	450	80
	10	7 1/2	5		
6	15	10	7 1/2	650	115
	20	15	10		
8	25	20	15	900	160
	30	25	20		
10	40	30	25	1,500	240
	50	40	30		
12	60	50	40	2,500	390
	75	60	50		

Use the 14-series bases for motors up to 175 hp. Use the 16-series bases for motors up to 250 hp.

The choice of base for a given motor is made with reference to the maximum bolthole spacing (Tables 14-71 and 14-72) and weight limitation of the base. If your motor weight is more than allowed for a given base, select the base from the maximum-weight column.

7. If it is found that the required overhang of the motor is greater than the standard base permits, the drive is not practical as laid out. By applying one or more of the corrective measures listed on page 1035, almost all drives can be accommodated.

---

* When $(D - d)/C$ is less than 0.200, the intersection of the strands is likely to fall off the paper. [illegible] pproxi- [illegible] he belt [illegible] pulley in proportion to T_1 and T_2 with the point of division nearer T_1. Draw [illegible] through the points of division.

a. Arrange the drive with the tight side of the belt running toward the pivot unless already done. (With some ceiling drives, more tension is obtained with the tight side away from the pivot.)
b. Increase pulley diameters and belt speed up to 6,000 fpm if possible.
c. Use a special-tannage belt and paper pulley, if not already done.
d. Raise the motor center up to 10 deg above horizontal.
e. Use a heavier motor, or weight the motor.
f. Use special long arms or the next larger size base.

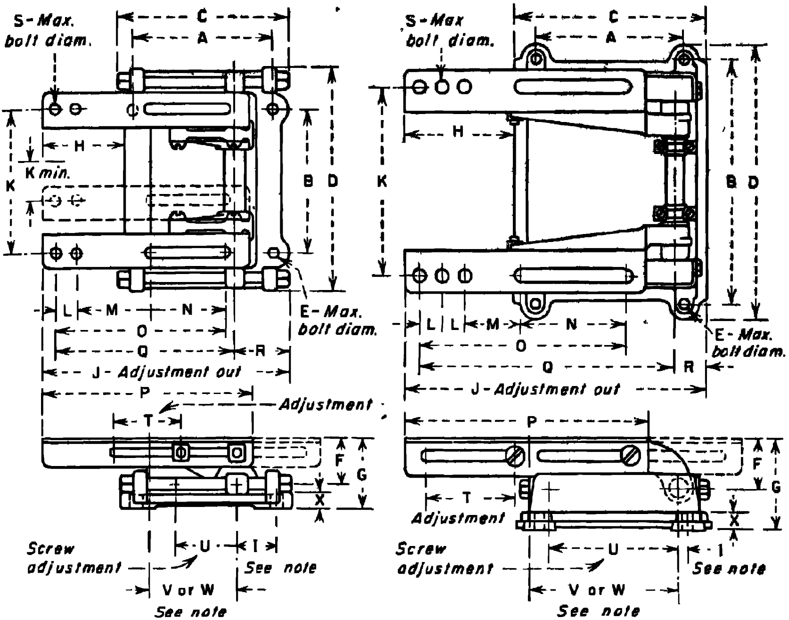
* Courtesy of Rockwood Manufacturing Co.

NOTE: Before installing base move pivot shaft to position indicated by dimension *I*. This permits future arm adjustments without affecting shaft centers or belt length. Dimensions *V* and *W* are suggested distances from center-line pivot shaft to center-line motor (assuming its location approximately one-half *O* dimension). Use *V* when tight strand of belt is nearest pivot shaft and *W* when tight strand of belt is away from pivot shaft. Greater transmitting capacity may then be obtained by moving angle rails out on arms, increasing *V* or *W*. Less transmitting capacity is obtained by decreasing *V* or *W*.



Base sizes Nos. 000 and 00.

Base sizes Nos. 0–12, inclusive.

FIG. 14-23. Diagram for Table 14-71.

Solution for Flat Belt Width and Thickness

Belt cross section must be sufficient to accommodate the maximum belt tension Tm which equals T_1 plus the centrifugal tension.

$Tm = MT_1$ where M is a factor taken from Table 14-70 for the type of belt and belt speed.

Belt thickness is limited by the diameter of the small pulley. From Table 14-74, take the belt thickness suited for the small pulley diameter. Belts suited for still smaller pulleys will give increased life, particularly at high speeds.

Use the corresponding value of Tm per inch of width (Table 14-74).

$$\text{Belt width } W = T_1M/Tm \text{ per inch of width}$$

When the width comes to a fraction, use the next larger standard width (see Table 14-75 for maximum width of belt for motor in use). These values may change with different motor manufacturers, and they should be consulted on wider widths.

To find the horsepower of a given belt, solve the following equation.

$$\text{Hp} = WTmV/33{,}000KM$$

Solution for Belt Length

For open belt calculate $(D - d)/C$, and from Table 14-76 find the value of J, and then multiply by C. Calculate $D + d$, and from Table 14-77, find the corresponding value of X. Where $D + d$ is not an even number or is not given in the table, it may be calculated.

Belt length equals $JC + X$. This is tapeline length. Deduct 1 per cent for elasticity on leather belts. On very short center drives where the pulley faces almost touch each other, add the belt thickness to each pulley diameter before figuring the belt length. This corrects the pulleys to the pitch diameter and gives the correct flat measure of the belt.

[*] Courtesy of Rockwood Manufacturing Co.

[†] This size and larger, also bases with 30-in. rails, have frame-constructed bottom plates. Add 8 lb to net weight for each 2-in. increase in length over 24 in.

[‡] Add 10¼ lb to net weight for each 2-in. increase in length over 40 in.

NOTE: Bases of all sizes can be supplied with bottom plates longer than standard at nominal extra cost (see price sheet). These usually are for bases that must fit over present foundation bolts, and bottom plate will be drilled to correspond to spacing of bolts in foundation. Raised foundations must be as wide and long as bottom plate.

NOTE: No. 14 bases only. Bases requiring angle-iron arm 40 in. or more long will be supplied with the 30-in. rail and bottom plate. Bases requiring shorter arms will be supplied with 24-in. rail and bottom plate.

When ordering specify horsepower, speed, make, type, frame number of motor. The latter very important. If not given, specify bolt size and spacing in motor feet. Give motor pulley diameter, kind and size of belt, driven speed or pulley diameter, shaft centers, and height of driven shaft above foundation top for Rockwood base.

Solution for Bearing Pressure

When the motor-pulley diameter is smaller than recommended by the motor manufacturer or wider than the standard width, the bearing pressure in the near-motor bearing may limit the belt tensions and should be checked as follows to see that it comes within the safe limits:

Nomenclature

G = the resultant of the tensions T_1 and T_2 under peak loads, lb
Z = the resultant of the tensions T_1 and T_2 at no load, lb
e = horizontal distance between the center of the motor pulley and pivot shaft, in.
Y = the perpendicular distance from pivot shaft to the line joining the pulley centers
W = motor weight
R = distance from center line of motor pulley to center of the far bearing
S = distance between centers of the two bearings
$Z = eW/Y$

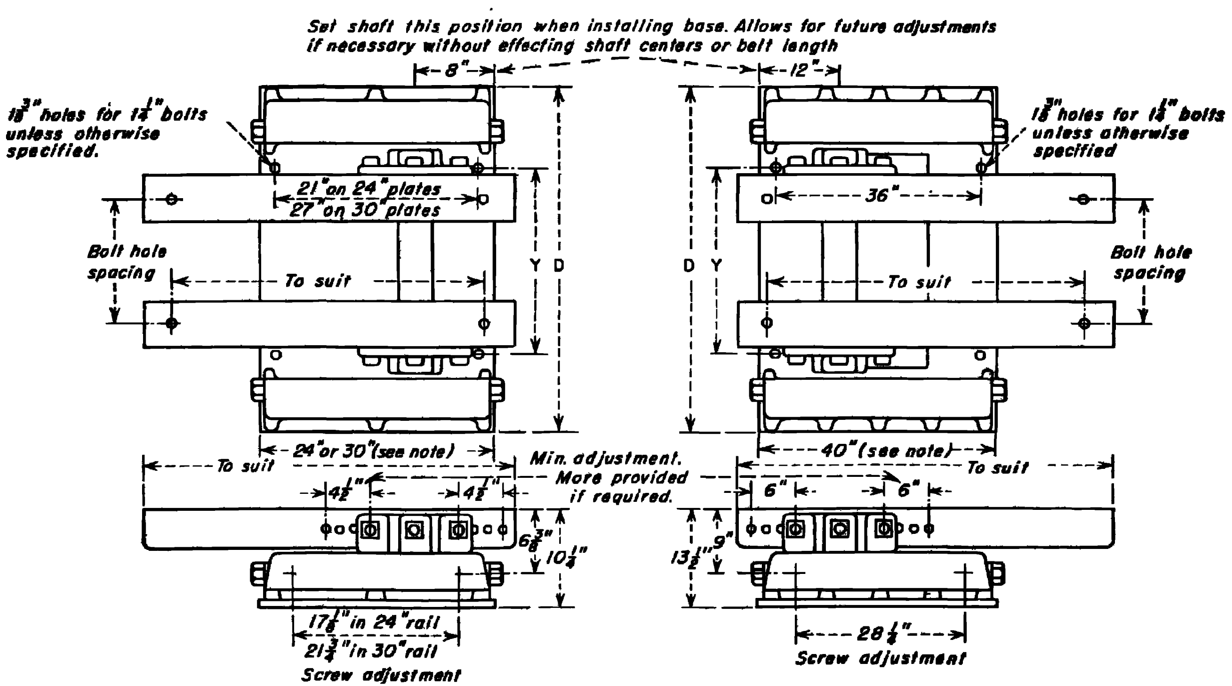
Using either Z or G, whichever is the larger, the maximum bearing pull = Z (or G) $\times$ (R/S).

Where R and S are not known, it is usually safe to assume that $R/S = \frac{4}{3}$.

The projected area for most motor bearings equals (shaft diameter inches)^2 $\times$ 2.5.

$$\text{Bearing pressure from belt} \quad \frac{\text{maximum bearing pull}}{\text{projected area}}$$

The maximum allowable bearing pressure varies with the speed, make of motor, and other conditions. Table 14-78a gives values that are generally safe.



Set shaft this position when installing base. Allows for future adjustments if necessary without effecting shaft centers or belt length

Layout diagram

If the calculated bearing pressure exceeds these values, the drive is not safe as laid out, and the same corrective measures as in (7), page 1033, should be applied.

The bearing pressure will be highest when the resultant belt tension is highest. When the tight strand is nearer the pivot than the slack strand, the resultant belt tension becomes highest at the peak load; and when the slack belt strand is nearer

1,800	60

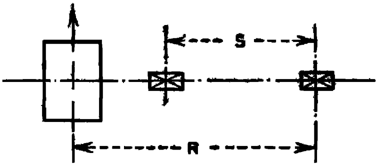

Fig. 14-25. Bearing pressure diagram.

the pivot than the tight strand, the resultant belt tension is highest at zero load. Using the fan-drive work sheet for data:

Example: $Z = eW/Y$
Let e = 13 in.
Y = 20.75
W = 1,300
G = 1,230
R/S = 4/3 (assume, since R/S is unknown)
Motor speed = 870 rpm

$$Z = (13 \times 1{,}300)/20.75 = 81$$

Use G = 1,230 as it is larger than Z = 814.

$$\text{Max bearing pull} = 1{,}230 \times \tfrac{4}{3} = 1{,}640 \text{ lb}$$
$$\text{Projected bearing area} = 3^2 \times 2.5 = 22.5$$

Using G, the bearing pressure from belt = (1,640/22.5) = 72.8 psi of projected area.

The maximum bearing pressure allowable from Table 14-78a above indicates that this figure will be satisfactory. This pressure comes only at extreme peak load so that the running pressure is below this figure.

INSTALLATION

Place the motor base on its foundations with the pivot shaft moved back about one-third the total take-up. With the pivot in this position, future increase in tension, if necessary, can be had without changing the center distance. Change the oil cups on the motor to the machine side of the motor. Put oil in the bearings, and with the belt in place start the drive up. Any small amount of misalignment can be corrected by turning one of the take-up bolts. Some small amount of tension increase or decrease may be necessary depending upon how close your original assumption of the peak load required was to the actual load. Some very heavy static friction loads, as in a heavy fan, may have to be freed before the motor will start the fan. This in no way is a reflection on the belt drive.

POSSIBLE PIVOTED-MOTOR-BASE-DRIVE DIFFICULTIES AND HOW TO OVERCOME THEM

Following the graphical solution for the pivot setting should eliminate most difficulties that are encountered. Vibration can in most cases be reduced to a minimum. Usually the cause suggests the cure. In some cases bracing the base support may eliminate vibration. Slightly more or less tension may be required. The bolts holding the motor to the base may be loose, or the cap bolts holding the arms to the pivot hubs may be loose. A worn bearing may be the cause. Checking the period of vibration of the motor with the belt or driven machine may help in locating the difficulty. Divide the belt length in feet into the belt speed in feet per minute. If this number is the same as the number of vibrations per minute, the belt is the cause.

MOTOR-ROTOR FLOAT

1. Often misalignment causes the belt to hold the motor rotor tight against the retaining colars, and there is no float at all. With correct alignment and with pulleys in the same plane, this should be eliminated.

2. Motor-rotor end play may not be sufficient. This should be increased to $\frac{1}{8}$ in. or reduced to practically nothing by using fiber washers.

The belt runs on the center of the pulley when load is on but runs off center with no load. Misalignment is the cause. If the belt will not run true by turning one of the center distance adjusting screws, the drive is out of level with the driven machine and should be corrected.

Advantages

To sum up, the main advantages of pivoted motor-base drive are

1. Complete dependability
2. Low maintenance
3. Constant correct tension (overcomes centrifugal tension)
4. Maintains its high efficiency over a wide range of loading (see Fig. 14-22)
5. Requires little space
6. Furnishes long life to belt and pulleys
7. Has a definite release point eliminating costly repairs to expensive machinery if a jam occurs
8. Easy drive alignment
9. Inexpensive to install

SPRING AUTOMATIC MOTOR BASES

The Automatic motor base is a device used in place of motor slide rails. It can be used in any position with any direction of rotation of the motor and no engineering is required for proper application. The base consists of a stationary member, motor plate, tensioning springs and adjusting screw.

Selection. To determine the size of base required, obtain the NEMA frame number from the motor name plate. Then refer to Table 14-78*b* of NEMA equivalents where the relation of frame numbers and base sizes is given.

In the absence of the NEMA frame number, ascertain the horsepower and speed of the motor and the distance between centers of the bolt holes. Then refer to Table 14-78c (Rating) and Table 14-78*d* (Dimensions). The slots are arranged to accommodate motors having standard NEMA frames. If the motor-bolt holes are not located to NEMA standards, use one pair of slots and drill two holes.

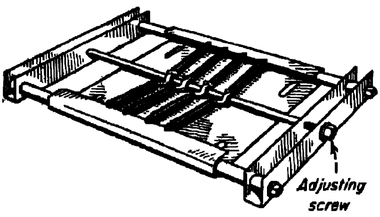

FIG. 14-26. Base 35 inverted to illustrate arrangement of springs.

On sizes 40, 45, 50, and 55 the motor support is articulated and may be separated so the slots will accommodate nonstandard motors.

For vertical down drive, *i.e.*, where the motor is side-wall mounted with the shaft horizontal and located above the driven pulley, specify "vertical" when ordering. "Vertical" bases should also be used where the motor-pulley diameter is smaller than recommended by NEMA standards and for all chain drive applications. "Vertical" bases are equipped with larger adjusting screws and with additional or heavier springs.

Figure 14-26 shows the spring arrangement and the simplicity of the base design.

The recent trend to increase motor horsepower without increasing the size of frame and the fact that the enclosed and explosion-proof motors are usually in larger frames, accounts for more than one size of base being listed under the same rating in Table 14-78c.

As the chain or belt stretches from normal use and wear, the tension is easily readjusted by turning a screw while operating under load.

Motor-mounting position, direction of pulley rotation, the type of belt or chain used or the nature of the load in no way affects its operation. Figure 14-27 shows a typical flat-belt installation.

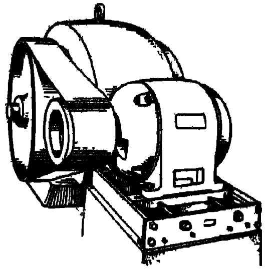

FIG. 14-27. A 50-hp motor mounted on a 55-R Automatic base.

The type R automatic was recently developed for motors up to 100 hp. The "R" stands for roller bearings, eight of them, which ride on cold-drawn steel tracks and support the motor. On the larger sizes, duplex springs and adjusting screws are used. The screws are connected by a roller chain, hence their action is synchronized. Turning either screw adjusts both springs simultaneously. This base is extremely compact and can be mounted in any position.

Installation. The automatic motor base is bolted to the motor feet and together they are bolted down as a unit. With the motor plate all the way forward, place the belt or belts on the drive. Apply tension to the drive by turning the adjusting screw shown in Fig. 14-26. This puts tension in the springs and belt by pulling the motor plate away from the driven machine. With the motor running, final tension adjustment can be made to handle peak loads.

CHAIN DRIVING

BY CHARLES R. WEISS

Chief Engineer, Chain Division, Link-Belt Company

INTRODUCTION

Mechanical transmission of power and speed conversion through chains is extensively employed because of the following factors:

1. Efficiency comparable to any means or method of positive driving. No slippage.
2. Flexibility and ease of application to meet widely varying industrial requirements.
3. Absorption of shock with less vibration than with gears.
4. Reasonable installation costs.

A chain drive consists of a chain connecting a *driver* sprocket to one or more *driven* sprockets. Pitch, either chain pitch or sprocket pitch, is the distance from center to center of two adjacent chain joints. The pitch circle of a sprocket would be the circle drawn through the centers of the chain joints of an endless chain, all the links of which are in mesh with all the teeth of the sprocket. The diameter of the pitch circle is called the "pitch diameter" of the sprocket. The number of teeth in the sprocket times the pitch of the chain in inches, times the rpm of the sprocket equals its pitch-line speed in terms of inches per minute, or dividing by 12 gives it in feet per minute (fpm).

The types of chain in most general use are treated in this subsection. However, many various other types of chain are produced, together with devices for adapting the various types of chains for use in conveyance.

OPEN-TYPE MALLEABLE-IRON AND PRESSED-STEEL CHAIN

In 1874, the first chain, the Ewart-type detachable shown by Fig. 14-28, was developed and is still produced for speeds up to 400-fpm for low-load non-abrasive installations for power transmission and, with suitable carriers, for conveyance. It consists of cast malleable-iron links designed to allow ease of

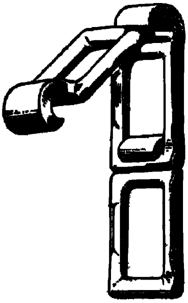

FIG. 14-28. Ewart-type detachable chain.

assembly and disassembly; usually operating on cast-tooth cast-iron sprockets. A number of common sizes are given in Table 14-79. In recent years this chain has also been produced in pearlitic malleable iron, increasing ultimate strength approximately 25 per cent with higher wear-resistant qualities, in bronze for corrosion resistance, and in chrome-nickel alloys, in the larger pitch sizes, for corrosion resistance.

In the smaller sizes the Ewart-type chain is made in heat-treated steel stampings with substantially identical performance characteristics at a slightly lower cost and is used to the greatest extent on agricultural machinery with special sprockets.

CLOSED-TYPE MALLEABLE-IRON CHAIN

The closed-type malleable-iron chain, as shown by Fig. 14-29, is used for chain installations of speeds up to 400 fpm where loads are greater than could be carried with open-type chain and where increased abrasive-resistant qualities are required. The sprockets used are identical with those for open-type chains. A number of common sizes are given in Table 14-80. Other stock sizes and special types are manufactured.

Table 14-80. Closed-type Malleable-iron Chains*

(Chains listed in the order of their strengths)

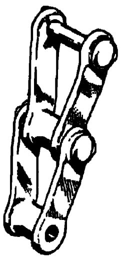

FIG. 14-29. Closed-type malleable-iron chain.

The closed type is also manufactured in pearlitic malleable iron for increased ultimate strength, in bronze for corrosive resistance, in stainless steel for corrosive resistance; and in chrome-nickel alloy for corrosive and heat resistance.

STEEL ROLLER CHAIN

Steel roller chain is constructed from steel side bars and hardened steel pins, bushings, and rollers. It will operate at speeds up to 700 fpm under heavier loads and with improved wear resistance as compared with corresponding sizes of malleable-iron chains. Parts may consist of stainless or alloy steel for special applications. This chain will operate on the same sprockets as malleable-iron chains, although for heavier loads a sprocket of more rugged design is required. Cast-tooth sprockets are generally used because of lower initial cost. However, operation at the higher speeds necessitates cut-tooth sprockets to increase chain life with smoother operation. In selecting sprockets, it is generally recommended, for increased chain life with more satisfactory service, that the smaller sprocket have not less than 10 teeth, which will usually limit ratios to not more than 5:1. A limited list of popular sizes is given in Table 14-81. Numerous other stock sizes are produced by various manufacturers, together with many special designs.

Finished-steel Roller Chain (ASA Standard). *Manufacture.* The links, rollers, pins, and bushings of this type, as shown by Fig. 14-30, are accurately made of high-grade steel, hardened, with the latter two being finish-ground. Owing to the precision manufacture, the pitches are held to close tolerances. This results in smooth operating action and increased chain and sprocket life. These chains are made of other materials, including bronze and stainless steel, to meet special operating requirements.

Selection of Chain Size. The revolutions per minute of the faster running shaft

limits the maximum pitch of chain that should be employed. A trial chain pitch should be selected from Table 14-82. If the single-width trial chain does not meet working-load-capacity requirements, proper multiple width of chain is selected.

Working Load Capacities. The average ultimate tensile strength for the various pitches of single-strand finished-steel roller chain are shown in Table 14-83.

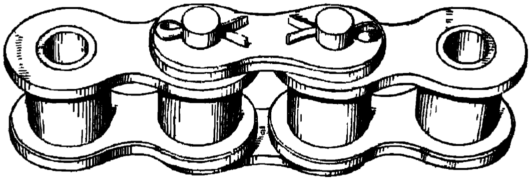

FIG. 14-30. Finished-steel roller chain.

The working load capacity based upon durability and ultimate strength is governed by horsepower, chain speed, and operating conditions. Permissible working loads for single-strand chain for various pitches and speeds are given in Table 14-84. The horsepower values listed in this table are based on 10-hr-per-day service, uniform loads, and good lubrication, where there is little shock or sharp variation in speed throughout a single revolution of the driven wheel. This rating can be adjusted to other periods of service and load characteristics by multiplying the known horsepower to be transmitted by the factors given in Table 14-85.

Table 14-83. Manufacturers' (ASA) Standard Sizes*

Chain No.	Pitch, in.	Average ultimate strength, lb	Wt per foot, lb
35	3/8	2,100	0.20
40	1/2	3,700	0.41
50	5/8	6,100	0.64
60	3/4	8,500	1 00
80	1 0	14,500	1 68
100	1 1/4	24,000	2 56
120	1 1/2	34,000	3.73
140	1 3/4	46,000	4 65
160	2 0	58,000	6 32
200	2 1/2	95,000	11 00

* Courtesy Link-Belt Co.

Chain Speeds. Finished-steel roller chains operate from 1,400 to 2,400 fpm depending upon number of teeth in faster running sprocket and chain pitch, as given in Table 14-84. Under certain operating conditions, roller chains can be operated at speeds up to 4,000 fpm, but the chain manufacturer should be consulted in such cases. Proper lubrication is essential for satisfactory chain life, and the importance of sufficient lubrication increases with the higher chain speeds.

Sprockets. Sprockets are all cut tooth, accurately machined from grey iron, cast steel, and forged or bar-stock steel, with pinions hardened and the larger sprockets

† Standard tolerances for bores are as shown below. Unless otherwise specified, the tolerance limits will be observed as standard

Bores, in.	Tolerance limits, in.	
Less than 2	+0.002	−0.000
2 and less than 3	+0.003	−0.000
3 and less than 4	+0.004	−0.000
4 and over.	+0.005	−0.000

usually hardened for durability. It is recommended for most satisfactory service that sprockets have a minimum of 21 teeth, but pinions with as few as 15 teeth are used to meet special conditions. Sprockets are available without hubs, with hubs on one or both sides, split type, demountable-rim type, and in the shear-pin type. To accommodate bore for the shaft, it may at times be necessary to increase the number of teeth in the smaller sprocket (see Table 14-86).

Velocity Ratios. A wide range of ratios is permissible. It is economy not to exceed 6:1, but larger ratios are possible. Where a larger ratio is required, a two-step drive is recommended.

Chain Care. Lubrication of chains should be sufficient effectively to oil the contacting surfaces of the chain joints and sprockets. Experience indicates that the desirable method is influenced by chain speeds and power transmitted (see Table 14-87). Consideration should be given to the use of chain casings, properly designed. Open running drives should be demounted and cleaned regularly with solvents, care being taken to reoil bearing surfaces copiously before reinstalling. Proper chain tension and alignment of sprockets are necessary for satisfactory chain life.

Table 14-87*

Chain speed	Lubrication method	
	Automatic	Manual
Under 600 fpm	Bath or splash	Oil cup or brush
600–1,500 fpm	Bath or splash	Oil cup (rapid drip)
Over 1,500 fpm	Pump or disk	Not recommended

SILENT CHAIN

Manufacture. A silent chain consists of a number of flat leaves contoured to provide teeth at both ends and connected by various types of pins to form a flexible, continuous rack in a wide variation of widths. Precision tools are used in the manufacture to maintain close control over size of hole, contour, pins, and bushings, where used, ensuring accurate pitch. Links are made of heat-treated high-carbon or alloy

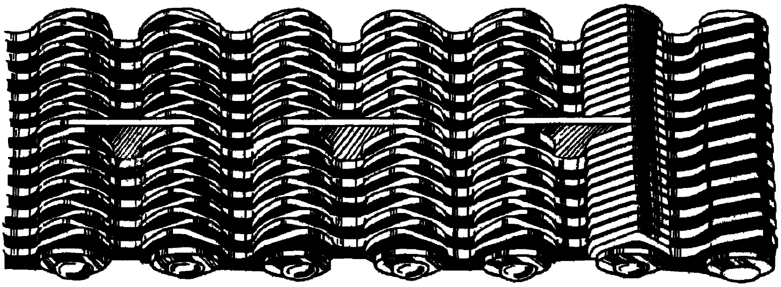

FIG. 14-31. Middle-guide silent chain.

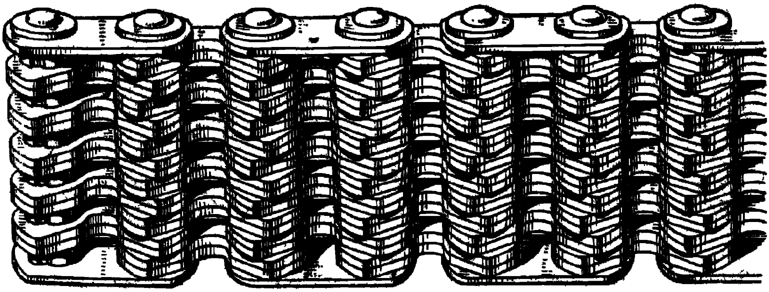

FIG. 14-32. Side-guide silent chain.

steel. Pins may consist of a single pin, bushed or unbushed, or a pair of pins with rocker faces. All joint parts are hardened for wear resistance.

Chain Guiding on Sprockets. Two classes of arrangements are used:

1. Flange links as a component part of the chain, known as the middle-guide type (Fig. 14-31) and (2) the side-guide type (Fig. 14-32)

Selection of Chain Size. The revolutions per minute of the faster running shaft limits the maximum pitch of chain that should be employed. Select a trial pitch size from Table 14-88.

Table 14-87*a*. Oil Viscosity for Silent Chain

Ambient temp., deg F	*SAE viscosity No.*
20–40	20
40–100	30
100–140	50

Where quiet operation is essential, use should be made of smaller pitches and wider chains, conservative ratings, and not less than 25 teeth in the faster running sprocket. The approximate maximum width of chain that may be used is 16 times the pitch.

Working Load Capacities. The working load capacity, based on durability and ultimate strength, is governed by horsepower, chain speed, and operating conditions. After selection of trial pitch size, reference should be made to Table 14-90, which gives horsepower ratings for various pitches of chains per inch of width. This rating is governed by a combination of rpm and number of teeth in small sprocket. The horsepower values listed in this table are based on 10-hr-per-day service, uniform loads, and good lubrication, where there is little shock or sharp vibration in speed throughout a single revolution of the driven wheel. This rating can be adjusted to other periods of service and load characteristics by multiplying the known horsepower to be transmitted by the factors in Table 14-85. Small sprockets must be checked to determine that maximum bore size will accommodate shaft necessary to transmit required horsepower.

Table 14-88. Silent Chain, Speed and Pitch Sizes*

Rpm of small wheel	*Trial pitch*
4,000–6,000	3/8
3,500–4,000	1/2
2,500–3,500	5/8
2,000–2,500	3/4
1,500–2,000	1
1,200–1,500	1 1/4
900–1,200	1 1/2
Below 900	2

Chain Speeds. For long life and low maintenance silent chains should be operated at maximum speeds from 1,400 to 3,500 fpm, depending on pitch and number of teeth in small sprocket. Silent chain drives under certain operating conditions are functioning successfully at chain speeds in excess of 5,000 fpm.

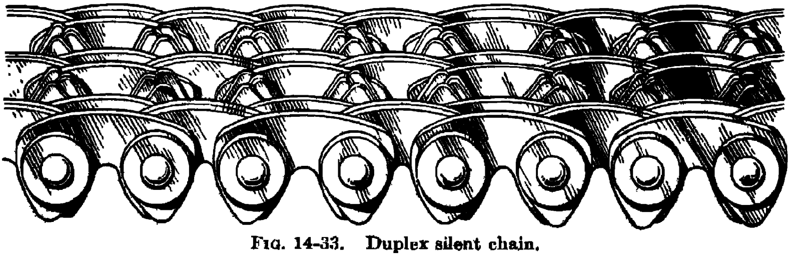

Fig. 14-33. Duplex silent chain.

Sprockets. All sprockets are of the cut-tooth type, accurately machined from gray iron, cast steel, and forged or bar-stock steel with pinions hardened and the larger sprockets either hardened or unhardened. It is recommended for most satisfactory service that sprockets have a minimum of 21 teeth (25 teeth where quiet operation is essential), but pinions with as low as 17 teeth are used. Sprockets are available without hubs, with hubs on one or both sides, in the split type, and in the shear-pin

type. To accommodate bore for the shaft, it may at times be necessary to increase the number of teeth in the smaller sprocket (see Table 14-89).

Velocity Ratios. The most desirable ratios for this chain range from 1.1 to 6:1. Large-ratio drives are less economical in both first cost and maintenance than comparable double-reduction drives would be.

Duplex or Double-back Type. The duplex or double-back type unit (Fig. 14-33) is constructed of silent chain parts so assembled that there are driving teeth on both sides of the chain. Sprockets can be driven from both its surfaces. It is particularly

† For best results, smaller sprocket should have at least 21 teeth.

In order to determine the exact center distance required, it is first necessary to compute the correct number of pitches for the approximate desired center distance. The following three steps are necessary to arrive at the solution of the number of pitches required:[1]

1. Subtract the pitch diameter of the smaller sprocket from the pitch diameter of the larger sprocket.

---

[1] This method takes into consideration the fact that the length of chain around a sprocket is less than the circumference of the pitch circle because the chain links describe a series of chords within the pitch circle.

Table 14-91*

Characteristics	Types of chain			
	Silent	Finished steel roller	Steel roller	Malleable or pressed steel
For use in low speeds, such as elevator and conveyor chain, where lubrication and cleanliness are impractical†	..	2	1	1
Light and heavy power-transmission primary drive	x	x		
Power-transmission secondary drive	..	x	x	x
Light conveyor and elevator work as conveyor or elevator chain under clean conditions not necessarily lubricated†	..	x	x	x
Heavy conveyor and elevator chains	..	..	x	x
Speeds up to 400 fpm	x	x	x	x
Speeds up to 700 fpm	x	x	x	
Speeds over 700 fpm	x	x		
Ratios up to 5:1	x	x	x	x
Ratios up to 10:1	x	x		
Ranking as to quietest, smoothest, and most efficient drive at equal speeds	1	2	3	4
Sprockets				
Cut tooth	x	x		
Cast tooth	..	..	x	x

* Courtesy Link-Belt Co.

2. Divide this difference by twice the desired chain centers.
3. Find in Col. *A* in Table 14-93 the value next larger than the result obtained by step 2, and use the corresponding values (in the same line) from Cols. *B*, *C*, and *D* to solve the following equations:

Centers

$B \times$ pitch = no. of pitches between sprockets
$C \times T_1$ = no. of pitches on smaller sprocket
$D \times T_2$ = no. of pitches on larger sprocket

where T_1 = no. of teeth in smaller sprocket
T_2 = no. of teeth in larger sprocket

The sum of these three calculations in step 3 is the number of pitches of chain required for the center distance used. However, if this value works out to a fractional number of pitches, it is necessary to perform additional calculation to obtain the proper center distance, except when the fractional number of pitches is slightly less than the nearest whole number, which difference will take care of desired coupling slack. So select the nearest whole number to the calculated number and proceed as follows:

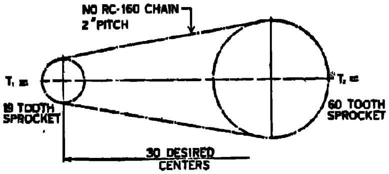
For All Types of Chains

If the Number of Pitches Selected Is Less than the Calculated Length. Subtract the number of pitches selected from the fractional number of pitches. The result is then multiplied by the pitch, and to this is added the amount of coupling slack desired. Divide this sum by value B, and subtract the result from the center distance used in the original calculations (refer to Example 1). Use an even number of pitches where

Example 1. When Centers Must Be Decreased to Suit Chain Length.



T_2 = 60-tooth sprocket, pitch diameter = 38.215 in.
T_1 = 19-tooth sprocket, pitch diameter = 12.151 in.
26.064 in.

$$\frac{26.064 \text{ in.}}{2 \times 30} = 0.43440$$

Then from Table 14-93,

Value A = 0.43445
Value B = 1.8014 × (30/2) = 27.021
Value C = 0.3569 × 19 = 6.781
Value D = 0.6431 × 60 = 38.586/72.388 pitches required for 30-in. centers

Specify 72 pitches, assuming that $\frac{1}{16}$-in. coupling slack is desired. Decrease center distance by

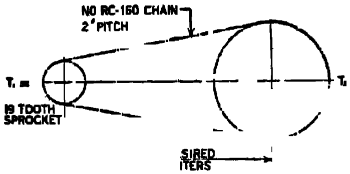
$$\begin{array}{l} 72.388 \\ \underline{72.000} \\ 0.388 \times 2 = 0.776 \text{ in.} \\ \qquad\qquad + \underline{0.062 \text{ in.}} \text{ slack for coupling} \\ \qquad\qquad\quad 0.838 \text{ in.} \\ 0.838 \text{ in.} \div 1.8014 = 0.465 \text{ in.} \end{array}$$

Then the correct center distance for this drive is

$$30.000 \text{ in.} - 0.465 \text{ in.} = 29.535 \text{ in.—say } 29\tfrac{17}{32} \text{ in.}$$

If the Number of Pitches Selected Is More than the Calculated Length. Subtract the fractional number of pitches calculated from the number of pitches selected, and multiply by the pitch. From this subtract the amount of coupling slack desired, and divide by value B. Add the result to the center distance used in the original calculations (refer to Example 2).

Example 2. When Centers Must Be Increased to Suit Chain Length.



T_2 = 60-tooth sprocket, pitch diameter = 38.215 in.
T_1 = 19-tooth sprocket, pitch diameter = 12.151 in.
26.064 in.

$$\frac{26.064 \text{ in.}}{2 \times 29} = 0.44938$$

Then from Table 14-93

Value A = 0.45010
Value B = 1.7860 × (29/2) = 25.897
Value C = 0.3514 × 19 = 6.677
Value D = 0.6486 × 60 = 39.916/71.490 pitches required for 29-in. centers

Specify 72 pitches, assuming that $\frac{1}{16}$-in. coupling slack is desired. Increase center distance by

72.000
71.490
0.510 × 2 in. = 1.020 in.
−0.062 in. slack for coupling
0.958 in.
0.958 in. ÷ 1.7860 = 0.536 in.

Then the correct center distance for this drive is

29.000 in. + 0.536 in. = 29.536 in.—say $29\frac{17}{32}$ in.

Relative Position of Sprockets

Careful attention should be given to the relative positions of shafts. Satisfactory operation can be secured with the drive at any angle to the horizontal if proper consideration is given to tension adjustment (see Fig. 14-34). Certain positions require less care and attention and are therefore less apt to cause trouble.

Tension-adjusting Devices

Means for adjusting tension will prolong chain life particularly when the position of the drive approaches the vertical. On positions approaching the horizontal, the chain itself acts as a tensioner. Regardless of position, a drive subject to pulsations and shocks requires some form of adjustment. The methods employed are either the standard slide rails of the motor or an idler sprocket mounted for automatic or manual adjustment. It is essential to locate idler sprockets on the slack or non-load-carrying side of the chain and preferably as close as possible to the driving sprocket. All idler arrangements should provide for no less than three teeth of the idler being in contact with the chain. Installations of both manual and automatic idlers are shown by Fig. 14-35.

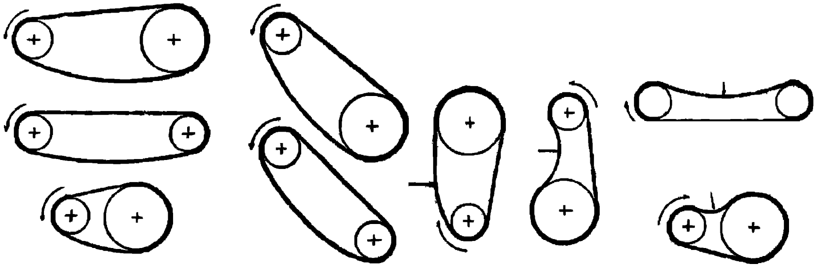


Fig. 14-34. Shaft positions for chain driving.

INSTALLATION

Alignment. Care should be exercised in the alignment of chain drives to obtain maximum service life with satisfactory performance. Proper alignment is particularly important with high-speed installations where silent and roller chains are used. The following checks should be made of the drive installation:

1. By checking the distance between the ends of the shafts on both sides of the sprockets it can be seen whether the shafts are parallel. These distances must be equal (Fig. 14-36).

2. A spirit level should be used on the sprocket shafts to see that they are level (Fig. 14-36).

3. Alignment of the wheels should be checked by the use of a straightedge along the face of the two wheels. On center-guide silent chain drives, this test should be made on center groves of sprockets (Fig. 14-36)

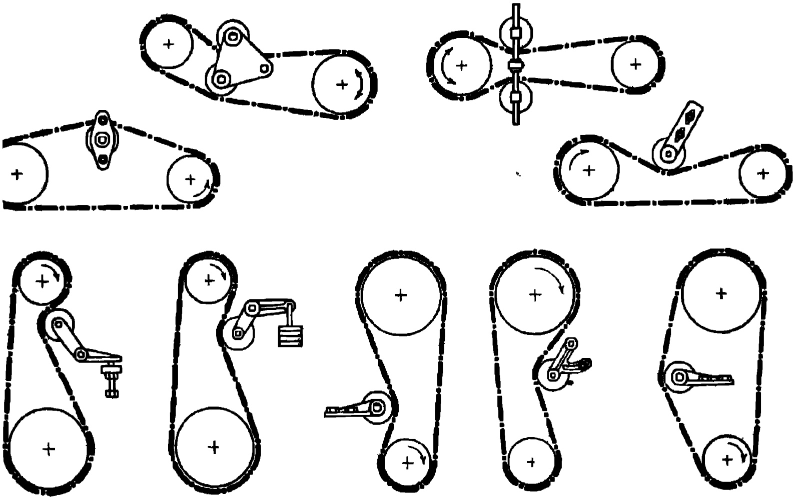

FIG. 14-35. Installation of manual and automatic idlers.

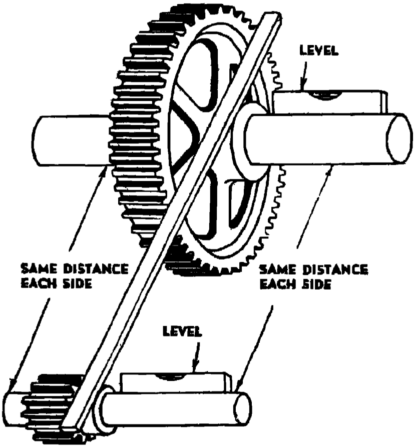

FIG. 14-36. Method for aligning sprockets.

4. Bearings should be sufficiently rigid to maintain alignment as originally mounted.

5. Sprockets should be located as near as possible to shaft bearings.

After drive is started, the alignment can be checked by inspecting the sides of the sprocket faces. This is particularly necessary if one sprocket is on the shaft of a motor that has shaft float. Wear on faces indicates wheel misalignment, which should be immediately corrected.

Coupling of Chain. Chains may be most easily coupled by lapping the ends over and engaging the teeth of the larger sprocket, which will act to hold the ends together while the coupling is made. In some cases it may be expedient to use the special coupling tools produced by the chain manufacturer. Some silent chains are designed to operate in one direction only, and care must be taken with this type of chain to see that the arrow on the side of the chain points in the direction of chain movement. Eward and closed-end pin-type chains will operate most satisfactorily if the hook or barrel end is run ahead of the bar end.

Tension. Owing to varying conditions, the amount of tension on a chain is difficult to prescribe. As a general rule, however, this tension should be less than that of a leather belt because a chain does not depend on tension for its tractive power. It is well to arrange for adjustable centers, if possible, in order to maintain a uniform amount of slack. In the case of vertical drives and in cases where there is likely to be considerable fluctuation in speed, irregularity of load, and considerable stopping and starting, chain should be run comparatively taut.

CASING

Chain-drive casings are used to exclude foreign materials which would cause excessive chain-joint wear; to provide means for adequate chain lubrication; to promote safety; and to improve the appearance and maintenance of cleanliness of the installation. Generally there are two types of casings produced: the oil-retaining casing and the oil- and dusttight casing. The first is most commonly used because of its low initial cost, but the latter will be found to be less expensive over a period of time where the chain must operate in an atmosphere laden with abrasive materials. Where absolute cleanliness is required, the latter type will prove the most satisfactory. For methods of lubrication see Figs. 14-37, 14-38, and 14-39.

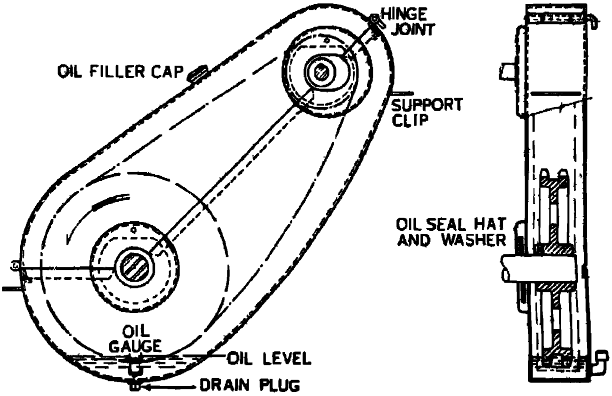

Fig. 14-37. Casing for splash lubrication.

CORROSION- AND HEAT-RESISTANT CHAINS

Corrosion Resistance. The rate of corrosion of a metal is dependent on many variables such as temperature, concentration, and degree of aeration of the corrosive agent which must be taken into consideration in the selection of the material used in the chain. Care must be taken to avoid electrolytic action, or chains will show excessive corrosion. There are two general types of chain for corrosion resistance:

1. Standard chains, which are galvanized, cadmium plated, or tinned.
2. Chains made of special materials, such as manganese, phosphor, aluminum, or silicon bronze, stainless steel (18 per cent chrome and 8 per cent nickel), or straight-chrome stainless steel (12 to 14 per cent chrome).

Chains of the first category will resist mild corrosive conditions, but the presence of more severe conditions will require that a chain of special materials be used. Manufacturers should be consulted for recommendations as to suitable material best to resist conditions to which chains will be subjected. It is highly desirable wherever possible to subject a small length of chain to the actual operating conditions before making a decision because of the fact that there are so many variations which materially affect results which on the surface seem of small importance.

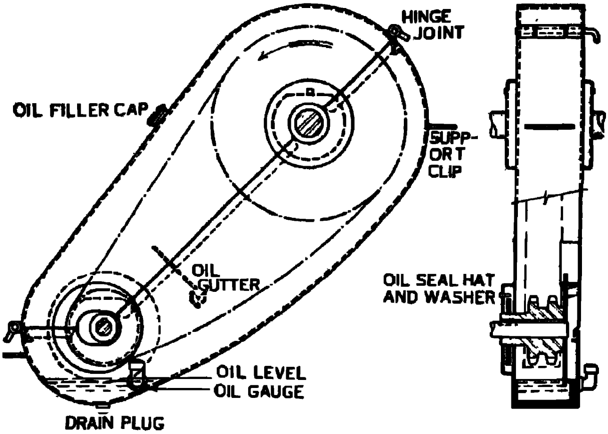

FIG. 14-38. Casing for oil-disk lubrication.

Heat Resistance. Metal loses strength rapidly with increase in temperature and is subject to oxidation and scaling. The factors that affect the life of a chain at elevated temperatures are the maximum temperature, the length of time at that temperature, and the atmospheric conditions. Standard chains will generally operate satisfactorily at temperatures up to 500°F, while some pearlitic malleable chains are

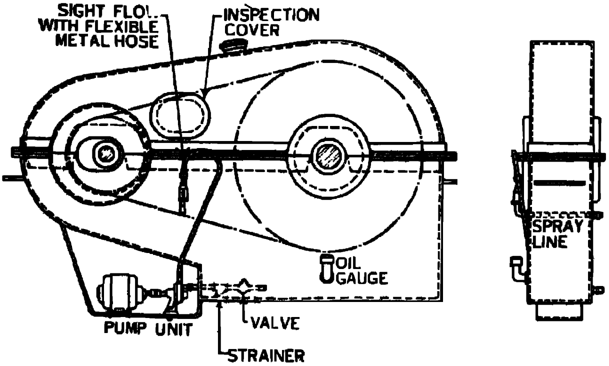

FIG. 14-39. Casing for force-feed lubrication.

operating satisfactorily at temperatures up to 1000°F. However, operating loads must be reduced with increase in temperature. Cast or unit-type construction is preferred for all high-temperature application to chains made up of a number of parts. For higher applications special alloys are available, and the chain manufacturer should be consulted. Many of these special alloy chains are operating successfully at temperatures up to 1800°F.

FLEXIBLE COUPLINGS

BY ERNEST HAGENLOCHER

Vice-President, Thomas Flexible Coupling Company

CAUSES OF SHAFT MISALIGNMENT

The most efficient means for transmitting power from a prime mover to a reduction gear or machine or from one machine to another is by flexible couplings of the proper selection and design.

Flexible couplings are designed to be used between two connected shafts to eliminate the stresses that would occur if the shafts were out of line and a solid coupling or through shaft were used. They are principally used to take care of misalignments that occur during operations. They also assist in the setting up of machines outside the erection shop since it is sometimes very difficult to get exact alignment in the field. Some types of flexible couplings also enable machines to be disconnected easily by the removal of the center ring assembly.

The misalignments that occur in operation result from

1. Settling of foundations
2. Wear in bearings
3. Temperature distortions
4. Vibrational disturbances
5. Belt tension, etc.

Machines should be aligned as accurately as possible when first set up. The full capacity of the coupling is then available to take care of subsequent misalignments.

The manufacturer's catalogue should be referred to for information as to the permissible amount of misalignment.

In parallel misalignment the two shafts are not in line but are displaced so they do not intersect (see Fig. 14-40*a*). In angular misalignment the center lines of the two shafts intersect at an angle (see Fig. 14-40*b*).

In practice there usually exists a combination of angular and parallel misalignments (see Fig. 14-40*c*). For this reason, it is a good practice to install a flexible coupling between the two connected shafts so that each machine can assume its normal position in its bearings without affecting the other machine and to eliminate undue strain on the shaft, cross pull, and end thrust on the bearings.

Consideration of what would happen in a diesel-engine and ammonia-compressor combination will indicate how serious it would be if a misalignment, either angular or parallel, were present and the two shafts were connected by a solid coupling. Since the four or more bearings cannot be held absolutely in line, reverse bending effects would occur in the shafts with each revolution. This would be disastrous both to the crankshaft of the diesel engine and to the crankshaft of the compressor.

The solid connection of a two-bearing motor and a two-bearing generator would subject the shafts to the same reversed stresses, and they would eventually break.

When a reduction gear is used, flexible couplings are required on both the high- and low-speed sides to take the strain off the pinion and its bearings as well as the low-speed gear and its bearings.

Similarly when three units are coupled together such as the motor-driven multiple-stage pump shown by Fig. 14-41, flexible couplings should be used to allow the shaft in each unit to run in its own bearings without any cross pull or end stresses from the other units.

TYPES OF FLEXIBLE COUPLINGS

There are many types of flexible couplings available, and new ones or improvements of older types are constantly being developed. However, of all the couplings on the market, there are only a few types that meet the requirements of present-day industrial operations. These are the ones that will be treated here.

Couplings can be roughly divided into two general types—single and double groups of elements. Single types are used for angular misalignment only, while double types are used for parallel and angular misalignment. Parallel misalignment is resolved into double angular by the action of the center member.

Dependability, long service, freedom from injury to connected machines, and low maintenance are the prime requirements for flexible couplings.

A flexible coupling except in a few special cases should drive like a solid coupling (especially important when the operating speed approaches critical); require a minimum of lubrication; have a minimum of backlash; provide for angular or parallel misalignment or both; have free end float under load and misalignment; have a minimum of wearing parts; and be noiseless.

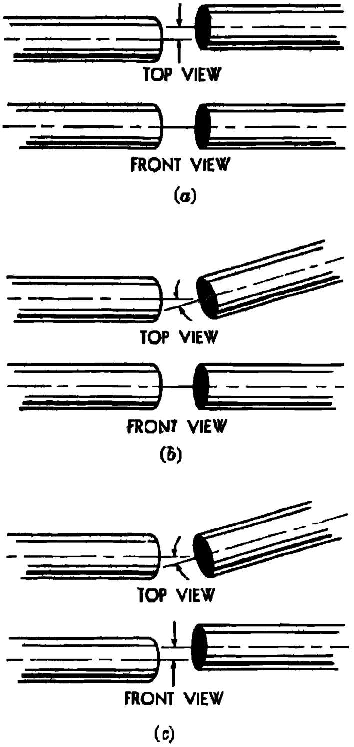

FIG. 14-40. The three ways of misalignment. (a) Parallel misalignment. (b) Angular misalignment. (c) Combination of angular with parallel misalignment in one plane.

Gear-tooth Type. Gear-tooth couplings consist primarily of two hubs with flanges, on the outer rim of which are gear teeth surrounded with an outer shell-type center member having internal teeth which mesh with the toothed flanges. The drive is from one toothed flange to the center member to the other toothed flange (see Fig. 14-42).

The method of supporting the floating center member and the shape of the gear teeth, as well as the method of retaining the lubricating oil, are the principal differences between the various makes of gear-tooth couplings.

Gear-tooth couplings are inherently of the double-engagement type and can be used for care of angular as well as parallel misalignment. A certain amount of clearance between teeth is necessary to permit the movement of the center member which acts as the flexible element in conjunction with the teeth on the flanges. The gear teeth actually act as a spline drive (see Fig. 14-43).

Grid-spring Type. The grid-spring type of coupling has a grid-formed spring which is placed in grooves which have been milled in the outer edges of two flanged hubs. The drive is through the sections of the spring grid that are carrying the load (see Fig. 14-44). Because of the constant working of the springs in the grooves, the coupling must be lubricated. This is accomplished by a bolted split cover over the flanges. This coupling is primarily a single-type coupling.

Pin and Bushing Type. Another form of coupling, the pin and bushing type, usually consists of a number of pins engaging with rubber bushings which are imbedded in holes in the opposite flange (see Fig. 14-45). This coupling is a single type. In operation this coupling depends upon the resiliency of the rubber for its flexibility which is subject to considerable stress in transmitting driving torque and accommodat-

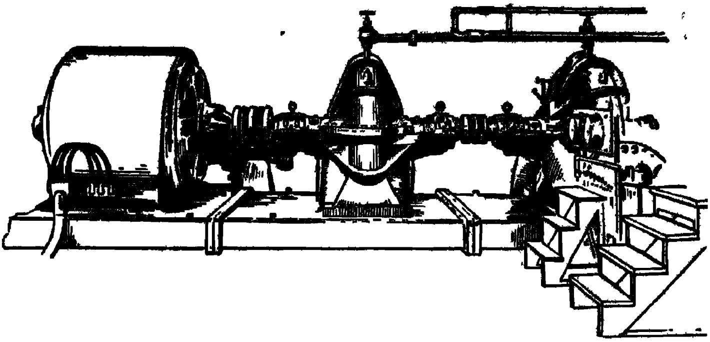

FIG 14-41. Motor-driven multiple-stage pump (coupled).

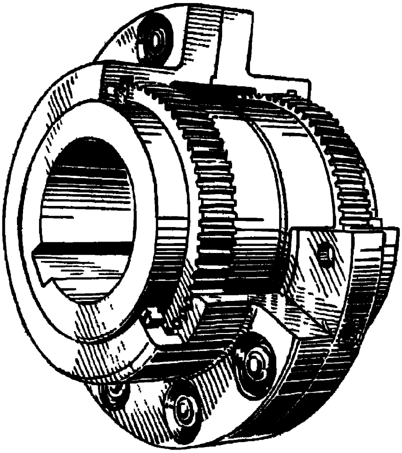

FIG. 14-42. Gear-tooth coupling.

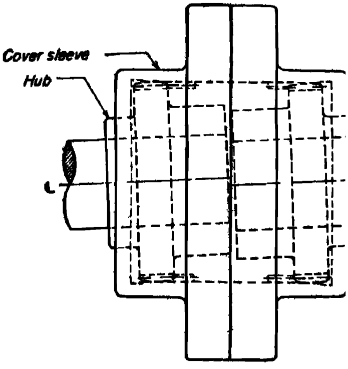

FIG. 14-43. Gear-tooth coupling in misalignment.

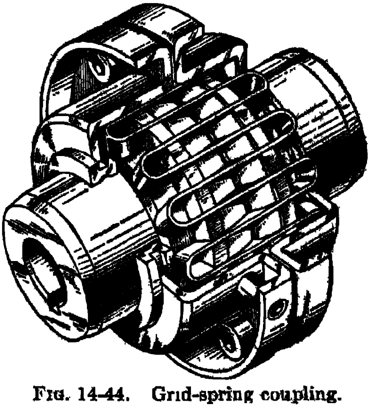

FIG. 14-44. Grid-spring coupling.

ing misalignment. In order to prevent the rubber bushings from being chafed by the action of the pins, they are usually provided with metal bushing inserts.

Chain Type. Chain-type couplings usually consist of two sprockets with hubs, one driving the other through a chain wrapped around the sprockets. The chain may be of the finished-steel roller or silent type (see Fig. 14-46).

Chain couplings are primarily of the single type and find application on smooth torque jobs. To obtain flexibility, there must be play and clearance between the chain and sprockets which result in a small amount of backlash.

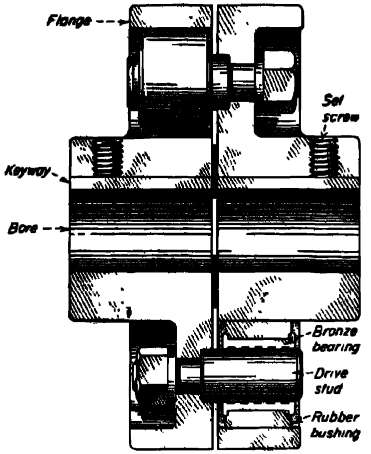

Fig. 14-45. Pin and bushing coupling.

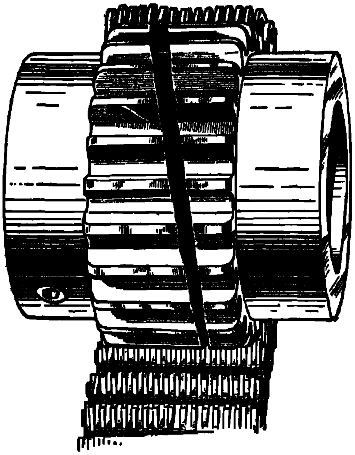

Fig. 14-46. Chain coupling.

To accommodate misalignment, the chain must be loose, which makes the chain carry the load in an offset manner. Some chain couplings have multiple rollers which reduce the friction on the teeth but place the strain on the pins.

Chain couplings require an enclosure to retain a lubricant and as a protection against foreign matter.

Block and Jaw Type. Block and jaw couplings are built on what is known as the Oldham principle, in which two hubs are provided with jaws which surround a square block, which acts as a center driving member (see Fig. 14-47).

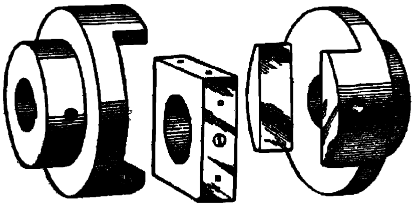

Fig. 14-47. Block and jaw coupling.

When such a coupling is operated under parallel misalignment, the block is free to slide provided there is no load on it.

If there is a load on the coupling and no misalignment, the jaw drives through a line contact on two corners of the block. As the coupling rotates under parallel misalignment, these corners rub back and forth. The greater the load, the more pressure there is on this line of contact. If operating under angular misalignment, line contact changes to point contact.

Clearance must be provided if there is to be any angular misalignment.

Metal-disk Type. The metal-disk coupling consists of two hubs with flanges to which are bolted flexible laminated-disk rings. These laminated disk rings in turn are bolted to a center member which may be in the shape of a round plate, a cylindrical spool, or a long shaft with flanges on the ends (see Figs. 14-48 and 14-49).

The principle on which the flexible metal-disk coupling operates is that any misalignment causes a slight displacement of the center member permitted by the bending of the disk rings. This is limited to 1 deg, which protects the metal fr[illegible]

The load is carried by the metal of the disks in direct tension between the bolts. There is no driving through spring action. The metal used in the disks is a specially designed alloy which has extremely high fatigue resistance.

This type of coupling drives like a solid coupling but has flexibility to take care of both kinds of misalignment either singly or in combination as well as providing free end float under load. There are no wearing parts, and no lubrication is required.

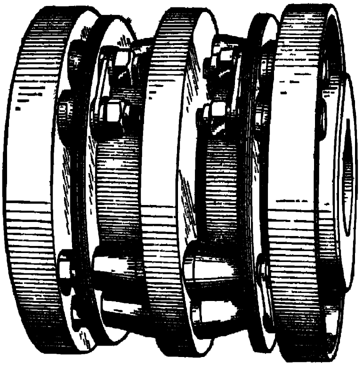

FIG. 14-48. Metal-disk coupling heavy duty, high speed.

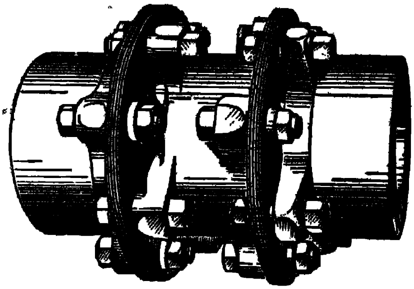

FIG. 14-49. Metal-disk coupling—heavy duty, medium speed.

All parts are in balance under any conditions of misalignment, which is especially important in high-speed couplings. The torsional characteristics remain constant regardless of length of operation since all parts are solidly bolted together.

In the double type of couplings, angular misalignment flexes the laminated disk rings with the total divided between the two rings. Parallel misalignment would also cause flexing of the disk rings, the total being divided between the two rings the same as if each disk ring were taking care of angular misalignment.

The flexible metal-disk ring coupling in the single type (see Fig. 14-50) is used for many purposes. The center ring is omitted, leaving one flexible laminated disk ring bolted to one flange and at alternate points to the other flange. In this form, since the parts are solidly bolted together, the concentricity is assured at all times, and the disk ring can be designed to carry any amount of weight. It can be used to support generator armatures where the generator has only one outboard bearing. The outboard bearing carries approximately half the weight of the armature, and the other half is carried through the coupling to the nearest bearing of the driver. Similarly, in motor-driven compressors the motor need have only one bearing—resulting in economies in material, floor space, and maintenance.

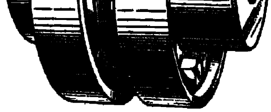

FIG. 14-50. Metal-disk single-type coupling.

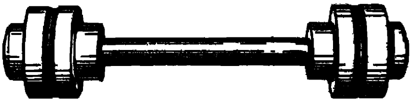

FIG. 14-51. Floating-shaft metal-disk coupling.

The Floating Shaft. The floating shaft is in reality an elongated flexible coupling and is generally used to span shaft-connected distances where the use of bearings is prohibitive. Many of the standard makes of flexible couplings can be used in conjunction with it. The metal-disk-type flexible coupling, when used in conjunction with the floating shaft, results in a very reliable and efficient drive since the farther apart the disk rings are the more misalignment can be accommodated. All parts of the metal-disk coupling type of floating shaft remain in perfect balance regardless of the period of operation since there are no wearing parts, and there is no change in the torsional characteristics. A floating-shaft metal-disk coupling is shown by Fig. 14-51. No pilot bearings are required.

SELECTION

Flexible couplings should be selected with care so that they will be large enough to accommodate the shaft sizes and suitable to withstand the stresses that occur owing to the torque load and to misalignment. The coupling should preferably have a minimum of backlash. With pulsating or uneven loads, backlash results in a hammer-like action which tends to shorten equipment life.

An important requirement in a flexible coupling is free end float *under load* so that no side thrust or axial strain will be transmitted to the connected machine. Generators and motors require a certain amount of free float in order to run in their magnetic center. Most machines are not provided with thrust bearings.

There is another important requirement when selecting couplings for machines that are placed some distance apart. Coupling hubs should be placed as closely as possible to the bearings of the connected machines, thereby shortening the overhang. The floating-shaft center member should be able to maintain its central position without the use of pilot bearings. The floating-shaft type of coupling is a very desirable method of connecting two machines since it permits greater misalignment, and this condition usually exists when machines are on separate foundations. Couplings of the flexible metal-disk type are held in exact centers because of their solidly bolted construction, and since there are no wearing parts, they always stay in balance.

Where there is a possibility of torsional vibration from medium or high speeds, serious thought should be given to flexible-coupling selection. If a coupling has wearing parts or is built upon the principle of springs or cushions, it is apparent that its torsional characteristics will vary with the degree of wear, the misalignment, and the load. Couplings of the flexible metal-disk type drive like a solid coupling, and their torsional characteristics are constant. This is of great importance since torsional-vibration stresses can be very harmful to the connected machines.

The factors that usually enter into the selection of the size of couplings are

1. The coupling must be able to transmit the torque.
2. The coupling must be able to withstand the type of load, *i.e.*, whether steady, fluctuating, or reverse.
3. The coupling selected on the basis of the above factors should have hubs that are large enough to accommodate the shafts of the units being connected.
4. The coupling should be of the type to withstand the stresses due to the speed at which it will run.
5. The misalignment to be encountered should be within the rating of the coupling.
6. Torsional stiffness.
7. The coupling must always remain in balance.

Most manufacturers supply complete information for standard applications. If the application is of a special nature, additional data should be obtained from the manufacturer before making the final selection. It is good practice to obtain the manufacturer's recommendation on applications where unusual conditions exist.

Referring to factor 1, calculate the maximum horsepower per 100 rpm on the coupling. Take the overload horsepower of the driver, divide by the rpm, and multiply by 100.

For factor 2, consult manufacturer's catalogue for type of load, such as compressor, pump, crusher, etc., and select a service factor that is dependent upon the characteristics of the driving unit.

Factor 3 is definitely a matter of dimensions.

In reference to factor 4, high-speed couplings are usually made of steel forgings machined all over and balanced. Over 1,000 rpm is usually considered high speed. Low-speed couplings are usually made of castings of steel, cast iron, or other metal.

If this misalignment (factor 5) is exceeded, some couplings will completely wear out, whereas in others only parts will wear.

Considering factor 6, if the installation is such that torsional vibration may be a factor, it is important to select a coupling possessing permanent torsional characteristics. If torsional vibration is present, it is almost impossible to absorb in the small space occupied by any make of coupling the energy necessary to change the period of vibration unless it be the floating-shaft type where the diameter of the intermediate shaft can be altered. This is most effective only if the floating shaft is at the center of the node of vibration.

Balance (factor 7) is especially important in couplings running at high speed, but it is also of great importance in slow-speed couplings where the center member is large, especially in applications such as ship drives, etc.

There are many applications where, by the use of a single-element coupling, the unit may be designed to save both space and cost. Single-bearing motors and single-bearing generators, when attached to their driven or driving units, introduce angular misalignment only. Such applications are found in diesel-driven generators on submarines, locomotives etc., and in motor-driven compressors etc. The cost of one bearing can be eliminated, and the amount of metal in the bedplate can be reduced in two ways—first, by shortening the bedplate owing to less space required; second, by lightening because less rigidity is required. Couplings for these applications must be capable of supporting the weight of the armature and still maintain exact concentricity between the shafts. Angular misalignment of 1 deg is usually permissible in such a design.

The floating-shaft type of coupling, *i.e.*, two single-element couplings connected by an intermediate tube or shaft, is being used more and more where greater misalignment is found. It also solves the problem of having the driving and driven units in different compartments or separated by fireproof walls, etc. Such cases are found in some pumping stations and aboard some ships. Also in marine work it is the ideal installation between the propeller shaft and the diesel engine. Couplings exceeding 20 ft in length have operated successfully. In such cases, however, the coupling must be capable of carrying the weight of the intermediate shaft and maintain its concentricity especially at medium and high speeds.

If thrust is present in marine applications, the application becomes special, and should be referred to the manufacturer for recommendations.

APPLICATIONS

In the ordinary installation of machinery, each unit in a coupled combination has its own bearings. This requires a "double type" of coupling to take care of the stresses that are set up if they were connected solidly to each other. This type of coupling has a center ring with connections on each side to the flanges which transforms the coupling into the equivalent of two "single types," each taking care of an angular condition resulting from the misalignment. This is easily recognized in some of the types and is illustrated here with the flexible-disk type of coupling (see Figs. 14-52, 14-53, and 14-54). If a double type of coupling is not used for this condition, the result of a single type is destructive cross pull on the bearings.

A single type of coupling is one that consists of two flanges with rubber bushings, chains, spring grid, or a single flexible metal disk ring connecting the two flanges. These are fundamentally able to take care of angular misalignment only, which is a condition which exists when the two shafts intersect at a point near the center of the coupling. This condition exists when a single outboard bearing is used to support a shaft or in a combination of two machines, one of which has only one bearing. Two single-type couplings connected with an intermediate shaft are the equivalent of a double-type coupling.

Low first cost is one reason for the popularity of some types of couplings. Manufacturers find it convenient to install these on units that are very competitive in price, and since their guarantee does not extend over a year, it is the customer's responsibility to take care of the replacements or maintenance after this period. Meanwhile, the coupling, if not of the right type, affects adversely the bearings and other parts of the unit. A little more thought given to the selection of a coupling would doubtless justify some additional expenditure initially and result in an installation that will require a minimum of maintenance or replacement.

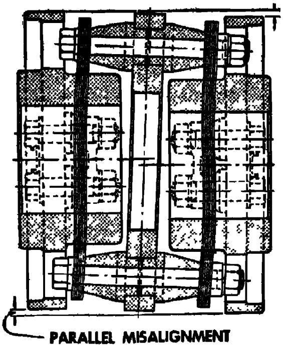

Fig. 14-52. Metal-disk coupling in parallel misalignment.

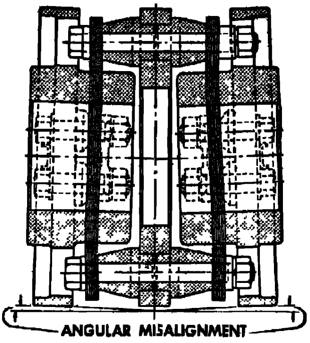

Fig. 14-53. Metal-disk coupling in angular misalignment.

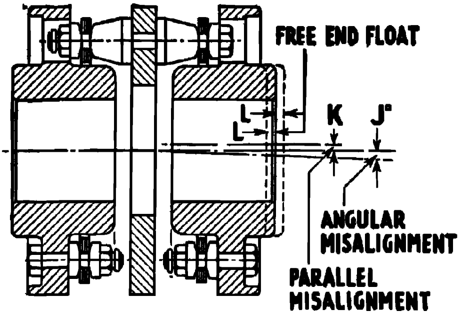

Fig. 14-54. Metal-disk coupling showing free end float.

MAINTENANCE

To avoid costly shutdowns of machinery, the couplings should be inspected on pumps, compressors, and other essential units periodically. Guard covers over couplings should be hinged to facilitate inspection.

Certain types of couplings require lubrication. If this requirement is neglected, wear will take place and will therefore do considerable damage to the coupling. Some couplings depend on lubrication to give free end float. If this is not present, side pressure is likely to be transmitted to the connected machines. This will damage the bearings or other parts. Where couplings are made with self-contained oil reservoirs, it is sometimes difficult to retain the oil at high speeds. This should be considered when making a selection.

If couplings of the single type are being used on installations that require the double type, wear and other troubles are multiplied.

For best performance couplings should always be placed close to bearings.

If trouble is experienced with a coupling drive, the initial check should be on the alignment of the shafts. This should be corrected if necessary. Then the coupling should be studied to see if it is the right type for the purpose. If not, it should be replaced with one that is more suitable and correct for the requirements.

When a coupling shows signs of strain or wear, it is economy to replace it at once before it damages the connected machinery.

VARIABLE-SPEED MECHANISMS

BY H. G. KELLER

Assistant Chief Engineer, Power Transmission, Link-Belt Company

INFINITE OR STEPLESS SPEED VARIATION

Infinite or stepless speed variation has extensive industrial application within two general categories:

1. Synchronizing the speeds of parts of the same machine or operations carried out in series to provide for uniform flow
2. Providing rapid, manual or automatic, flexibility in the operations of a machine for increased capacity, lower production costs, and higher precision standards

This subsection will treat the mechanical methods of stepless speed variation (see Sec. 17 for hydraulic systems and Sec. 16 for electric speed control). Mechanical systems have the advantages of being low in first cost, simple in construction and maintenance, and comparatively efficient in operation. Stepless speed variation, under load, may be obtained through the use of one or more of the following five mechanical principles:

A. Flat-belt type
B. Friction-disk or cone type
C. Ratchet or interrupted-motion type
D. V drives with adjustable conical pulley or pulleys
  1. Vari-speed-pulley type
  2. Interlocking dual pulleys, countershaft type
  3. Adjustable cone pulleys, parallel-shaft type
    a. Belt drive
    b. Chain drive
    c. Steel-ring drive
  4. Compound adjustable pulleys and interlocking dual pulleys
E. Controlled differential-gear system

In the selection of the type of speed-variation mechanism to employ, consideration should be given to some or all of the following factors:

1. Ratio of speed variation required
2. Torque or horsepower, in relation to speed requirements, throughout the range of speed variation
3. Operating conditions
    a. Source of power
    b. Uniform loading
    c. Moderate or heavy shock loading
    d. Necessity for frequent starting or reversal
    e. Braking effect required
4. Type of unit (open, semi-enclosed, enclosed) dust, fumes, weather, etc.
5. Space and mounting requirements
6. Accuracy of unit in respect to ability, under constant torque load, to duplicate ratio settings after previous adjustment
7. Per cent change of ratio accompanying change in torque

TYPES OF VARIABLE-SPEED MECHANISMS

Flat-belt Type. The flat-belt type of mechanism consists essentially of a flat belt operating with two conical (nonadjustable) pulleys with suitable belt guides and shifting means as shown by Fig. 14-55.

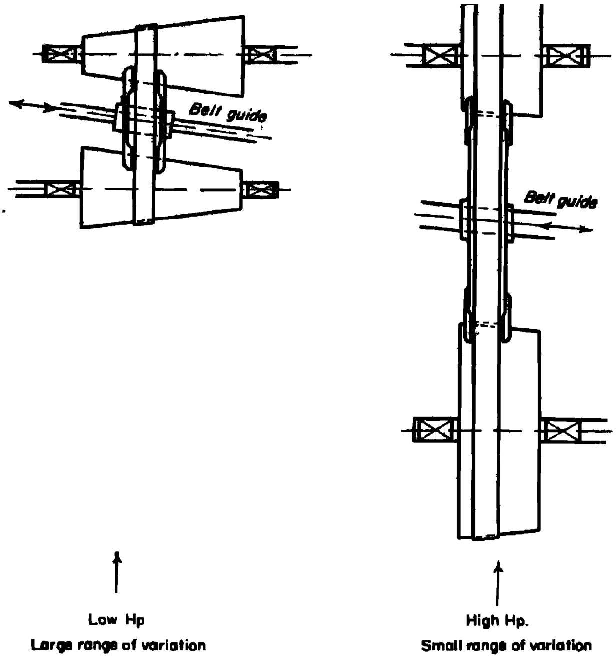

FIG. 14-55. Flat-belt type.

Two general types are in common use, although not available as standard transmission units. Flat-belt mechanisms are usually designed to suit specific applications.

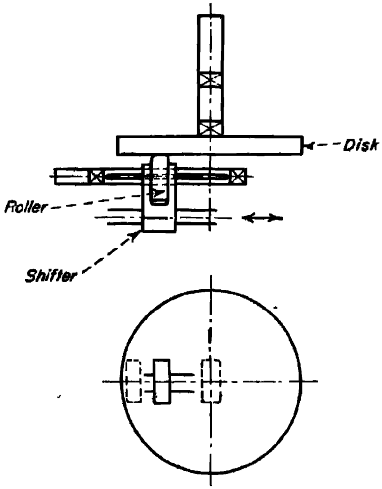

FIG. 14-56. Friction-disk type.

Friction-disk or Cone Type. One of the earliest forms of a mechanical speed mechanism consisted of a driver and a driven disk mounted at right angles to each other, and having a friction contact (see Fig. 14-56). Control of the relative speed of rotation of the two disks was maintained through varying the point of contact of the disks.

A friction-cone type of variable-speed drive is manufactured[1]* which utilizes the planetary system similar to that used in the differential drives. Three tapered rollers are used, supported in a carrier rotated by the input shaft. The rollers are free to revolve about their own centers and are mounted so that their tapered outer edge is parallel to the central axis of the machine (see Figs. 14-57 and 14-58). A steel nonrotating ring contacts the outer edge of the rollers.

---

* List of manufacturers of various units, designated by superior numbers, is given at the end of this subsection.

This ring is movable longitudinally so that the point of contact on the rollers may be changed to any position between either end of the rollers, thus varying the velocity at which they revolve. Pinions on one end of the rollers engage a ring gear connected to the output shaft.

The carrier supports each roller in double bearings located between the pinions and the cone. Bearings are shim-adjusted in assembly to assure proper contact between rollers and ring. Centrifugal force acting upon the roller during rotation presses the roller firmly against the ring. The small end of the tapered roller (the end giving the slowest, or reversed, speed when contacted by the ring at that point) is at the end of the roller opposite the sliding block Thus the lever arm of the roller in relation to the lever arm of the ring is the greatest during the slow speed, or reversed, operation of the output shaft, giving the greatest traction of the roller on the ring at that time.

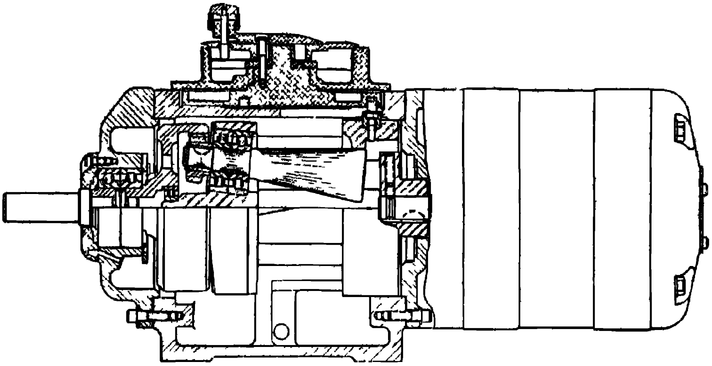

Fig. 14-57. Friction-cone type.

This unit is made in seven motor sizes from $\frac{1}{15}$ to 3 hp, and these units have speed ranges from approximately one-fifth motor speed down to zero. The same units are available for speed ranges which are equal on both sides of zero, the range being approximately one-sixth motor speed forward and reverse through zero. Motors and reduction-gear sets are available for integral mounting.

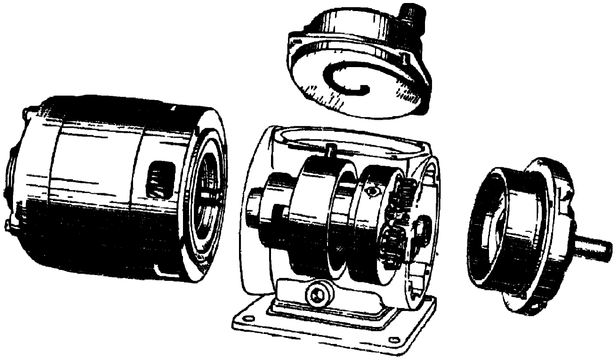

Fig. 14-58. Friction-cone type (exploded view).

Ratchet or Interrupted-motion Type.[2] The principle of the ratchet or interrupted-motion device is shown by Fig. 14-59. The amount of throw to the crank (thus the rotation of the output shaft) may be adjusted by varying the amount of eccentricity obtained on the input shaft through rotation of the double eccentrics. Another method is to provide a center pivot about which the crank arm rotates, and by changing the point of pivot of the crank arm, the amount of throw at the output end of the crank may be varied. Through the use of a ratchet or roller clutch, movement of the crank produces unidirectional rotation of the output shaft. Increasing the number of eccentrics, cranks, and clutch units will reduce the time lag between pulsations in the output shaft.

A unit of this type (shown by Fig. 14-60) is manufactured particularly for use with feeders and conveyors. This unit is rated at 3 hp, 250-rpm maximum input speed. The output-speed range is adjustable from 22 to 0.83 per cent of the input speed.

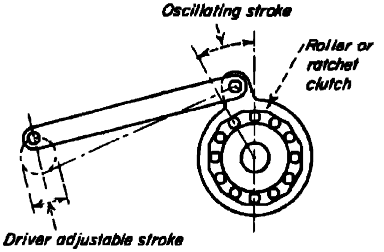

Fig. 14-59. Ratchet type (principle).

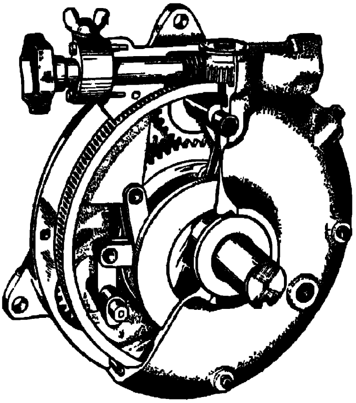

Fig. 14-60. Ratchet type.

V DRIVES WITH ADJUSTABLE CONICAL PULLEYS

The majority, in number of different types produced, of stepless speed-variation devices are modifications of V drives with adjustable conical pulleys. In general, they can be grouped under one of four subclassifications, though with some specific devices there will be an overlapping of the methods involved:

1. Vari-speed pulley
2. Interlocking dual pulleys, countershaft type
3. Adjustable cone pulleys, parallel-shaft type
4. Compound adjustable pulleys and interlocking dual pulleys

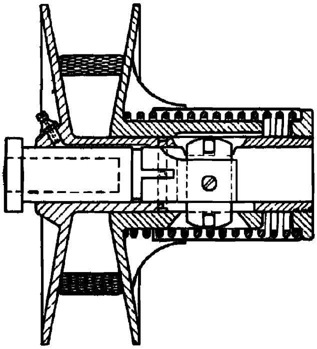

Fig. 14-61. Vari-speed pulley.

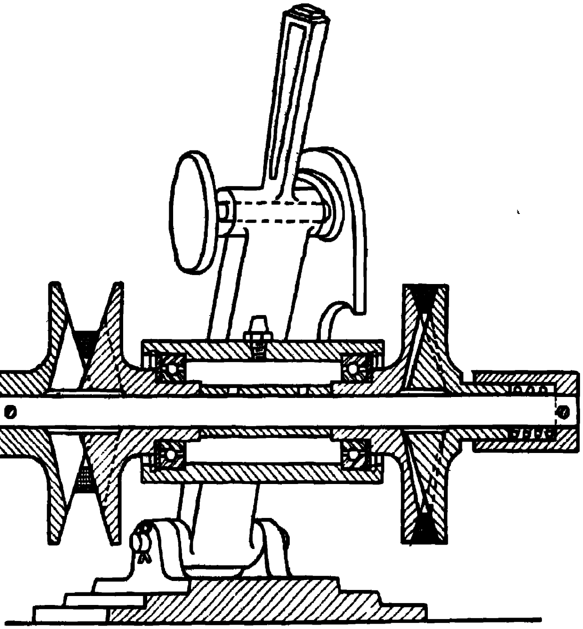
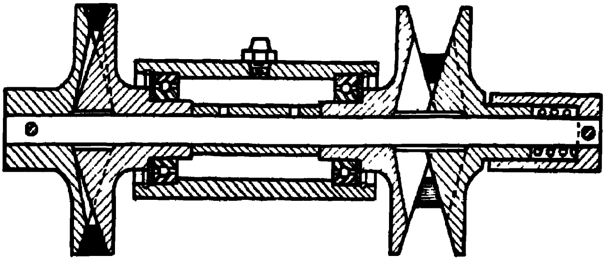
Vari-speed Pulley.[3] The simplest form of speed control, the vari-speed pulley, consists of two conical, or half pulleys, mounted on the motor shaft, one half being fixed and the other sliding laterally along the shaft. The sliding half generally has a loading spring pressing against its outer face (see Fig. 14-61). Provision is made for adjustable shaft centers, usually by means of a sliding motor base with screw-adjustable handwheel. When the motor is nearest the driven shaft, the V belt assumes the largest arc of contact on the pulley faces, with the operating effect of large pulley diameter. By turning the handwheel, the motor is moved away from the driven shaft, and the tightening of the V belt forces the pulley faces apart by compressing the spring, thus reducing the arc of contact of the pulley with the effect of smaller pulley diameter. The total variation in the shaft center distance varies from approximately 2 in. on the smaller sizes to 8 in. on the larger sizes.

Vari-speed pulleys are manufactured in a number of sizes for use with standard V belts, with capacities up to 7½ hp, 1,740 rpm, and ratios up to 4:1. They are also made in six sizes for use with multiple block-type V belts for motors up to 15 hp, 870 rpm, and ratios of 2¼:1. The maximum ratio obtainable with this type is 3:1 on some of the smaller motor sizes. A special belt may be used which combines the features of a V belt for contact between the V disks and a flat belt for contacting the driven pulley, with operating characteristics substantially the same as for standard V belts.



Slow speed position



High speed position

Fig. 14-62. Interlocking dual pulleys.

Interlocking Dual Pulleys, Countershaft Type.[4] The countershaft type of interlocking dual pulleys (Fig. 14-62) consists of two interlocking split pulleys mounted on a countershaft between the fixed driving and driven wheels. The two variable pulleys are connected on the shaft in such a manner that movement of one of the faces of one pulley, increasing the distance between the faces and thus reducing the effective pulley diameter, results in an equal amount of closure in the space between the faces of the other pulley, with increased effective pulley diameter on the second pulley. The countershaft is pivoted on its base (or in some cases on a sliding base) to allow lateral movement toward either the driver or driven shaft, which movement will result in a tightening of one belt and a slackening in the other. The effect of tightening one belt and slackening the other causes an automatic shift in the faces of the two pulleys equalizing the tension in both belts and resulting in a new ratio between their running diameters. Provision is made for locking the countershaft in the new lateral position.

Like the vari-speed-pulley type of drive, this device is economical in both first cost and maintenance but permits a greater ratio variation through the use of two adjustable wheels rather than one.

These units are made for use with standard V belts or combination belts to operate on both V and flat wheels. Sizes range up to 7½ hp at 2½:1 ratio, and ratios up to 10:1 may be obtained with some of the smaller horsepower sizes.

Adjustable Cone Pulleys, Parallel-shaft Type. The parallel-shaft type of adjustable cone pulley consists of two parallel shafts on which are mounted a pair of adjustable cone pulleys, with a belt, chain, or ring as the connecting medium. Provision is made for adjusting the spacing between the faces of the cones by a movement of one or both halves of the pulley in such a manner that, when the spacing of the pulley opening on one shaft is being increased, the spacing of the pulley opening on the opposite shaft is being decreased. Thus when the effective diameter of the pulley on the first shaft is being decreased, that of the opposing pulley is increased, and the necessary length of belt, chain, or ring to encompass the two pulleys is substantially the same.* A multiple of pulleys and belts may be mounted within a single unit.

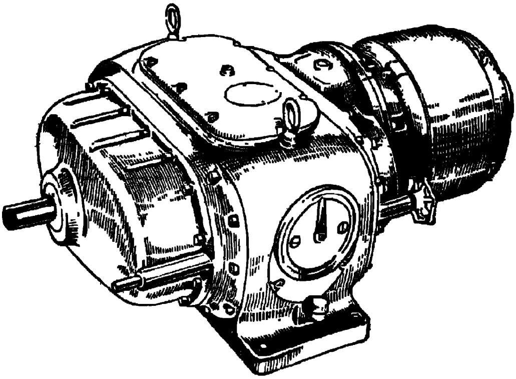


Fig. 14-63. Adjustable cone pulleys, parallel-shaft type, motorized with integral gear reduction.

Units of this general construction are invariably used where larger horsepower requirements are necessary. Most units are available with integral motors and gear reduction units (Fig. 14-63) with floor, ceiling, or wall mounting in horizontal or vertical styles.

Adjustable cone pulleys may be equipped with various accessories such as tachometers (mechanical or electrical type), electric control motors, or hydraulic control elements, with manual, semiautomatic, or full automatic control, cam or lever controls, etc. In fact, practically any known measuring or controlling instrument or element may be used to control variable-speed mechanisms provided a slight time lag can be allowed in order to allow the control to function. Beyond this much depends upon the ability to coordinate the signal of the control instrument or element with the variable-speed-control actuating means with sufficient accuracy to provide desired results. Generally speaking, most automatic controls are of the follower type; *i.e.*, a temperature, tension, speed, etc., is the signal element which sets in motion the variable-speed-control actuating means. In such a case, the variable speed control is attempting to respond to, and correct, an existent condition which is approaching the limit of temperature, tension, speed, etc.

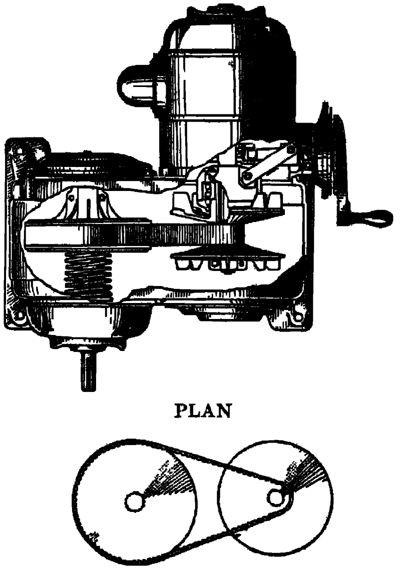
---

* Actually there is a difference. The correct length of belt to operate over 1:1 ratio pulleys with fixed shaft centers will not be long enough to operate on other than 1:1 ratio pulleys on the same shafts even though the sum of the pulley diameters in the second case be equal to the sum of the pulley diameters at the 1:1 position. On some drives adjustment is made by mechanical means, such as equalizing linkage or spring loading of one half of a pulley, while on others a convex curving of the V pulley faces tightens the belt as it approaches the 1:1 position.

Manufacturers, when specifying the maximum allowable ratio of speed variation, give the ratio from the highest to lowest output speed, not the amount of variation, higher or lower, that may be made of the output speed in relation to the input speed. Most units of this type are furnished with pulleys of equal size on both shafts, which allows the speed of the output shaft to be increased or decreased an equal amount from the speed of the input shaft. In such a case, if the speed of the input shaft is known, the maximum high or low speed of the output shaft may be calculated by multiplying and dividing, respectively, the speed of the input shaft by the square root of the specified speed variation of the unit. With a unit having a specified maximum speed variation of 9:1 and an input speed of 1,150 rpm, the maximum output speed would be the square root of 9 (or 3) times 1,150 for a total of 3,450 rpm. The minimum output speed would be 1,150 divided by 3, or 383 rpm (3,450 to 383 is a 9:1 ratio). Thus in this unit, the ratio of input speed to output speeds is 3:1 and 1:3.

The following discussion of specific applications of this device is divided on the basis of the type of connecting medium (belt, chain, steel ring).

Belt.[5] Devices are available for use with standard V belts or with special sizes of fabric and steel in rubber belts. These are manufactured in numerous sizes up to 75 hp at 3 :1 ratio, while some smaller units will provide ratios up to 6 :1 (see Fig. 14-64).



PLAN

ELEV.

FIG. 14-64. Adjustable cone pulleys, parallel-shaft type, motorized.

Several manufacturers produce devices for use with a special belt consisting of an endless-cord belt clamped between wood blocks whose ends, tipped with leather pads, are tapered at the same angle as the cone faces (see Figs. 14-65 and 14-66). Various sizes are produced up to 87-hp output at a 2:1 ratio. In the smaller sizes will be found units providing ratios up to 16:1.

Chains.[6] The PIV (positively, infinitely variable) type of transmission differs from the other types of V drives in that it does not depend upon friction for its tractive effort. The chain consists of bushed pin-joined cages, each holding a pack of flat hardened-steel laminations tapered at the ends to the same angle as the wheel faces. These laminations are free to slide from side to side, individually, with relation to each other (Fig. 14-67). This type of transmission utilizes an arrangement of conical-faced wheels having radial teeth cut into their faces (see Fig. 14-68). The wheels are so mounted on the shaft that immediately opposite the projecting tooth on one face of a wheel is a groove on the face of the opposing wheel. As the chain enters the V formed by the two wheel faces, the staggered teeth of the wheels push the requisite number of steel laminations transversely (at right angles to the chain travel) into position in the opposing tooth spaces to form the positive engagement which transmits the load. This engagement is complete before the load or pull on the slats is applied, and there is no further movement while they are under load.

The wheel faces are not straight cones but have a slight convex curve to maintain proper chain tension at all positions of speed variation. A hardened-steel shoe rides lightly on both the upper and lower strands of the chain to assure correct entry and engagement of the chain slats into the sprockets. The use of one on both the top and bottom strands allows the chain to be run in either direction. Splash lubrication is provided in the sealed case.

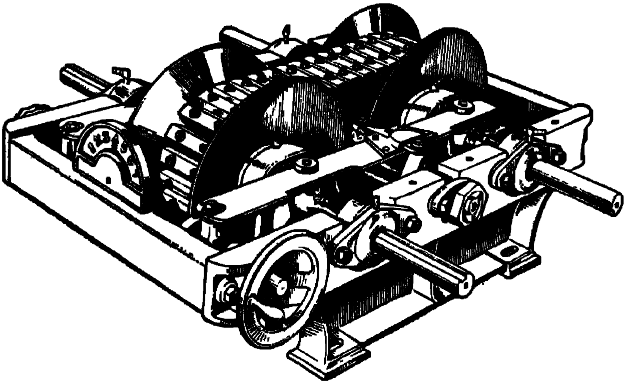


Fig. 14-65. Adjustable cone pulleys, parallel-shaft type, open.

Eight sizes are produced, in capacities from ½ to 25 hp, with maximum ratios of up to 6:1.

The VRD (variable roller drive) is of the parallel-shaft type with a pair of adjustable conical wheels and employs a roller chain of special design for the transmission of power between the wheels on the two shafts (see Fig. 14-69). The endless side-contact chain (Fig. 14-70) has openings in each pitch, or section of links, which provide a longitudinal (parallel to direction of chain travel) pocket for each of two hard-steel rollers which protrude sufficiently to contact the smooth-faced conically opposed disks. At each engagement of chain and wheels, with the opposed disks approaching at an acute angle, each pair of chain rollers is free to roll into driving contact with the wheels. The disengagement of the chain is likewise a rolling action. This device operates in a totally enclosed, oiltight housing, providing splash lubrication.

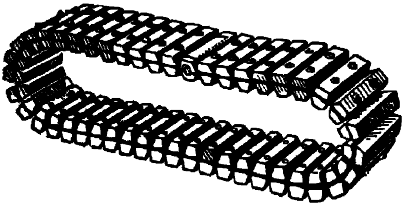

Fig. 14-66. Endless belt with leather-tipped blocks.

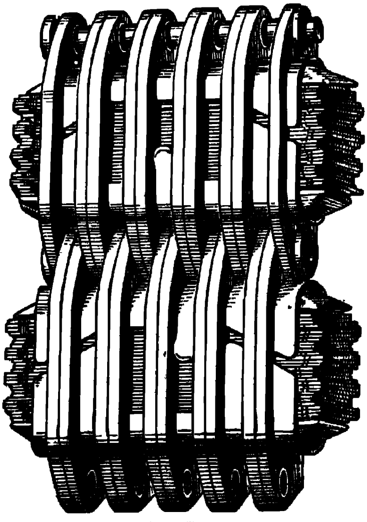

Fig. 14-67. PIV chain.

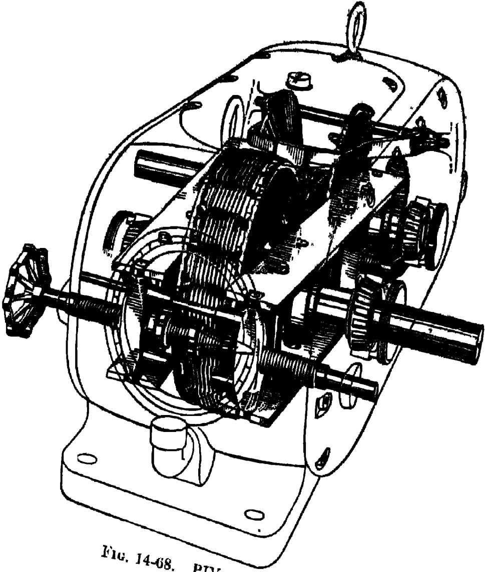

Fig. 14-68. PIV transmission.

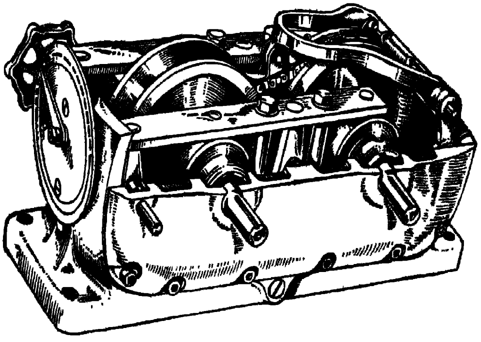

Fig. 14-69. VRD transmission.

The VRD unit is built in one size having a maximum rating of ½ hp and a maximum ratio of speed variation of 10:1.

Steel-ring Drive.[7] Steel-ring drive employs a circular steel ring running on variable conical pulleys to transmit the power between the parallel shafts (see Fig. 14-71). When a load is applied to the output shaft, the rotating ring shifts laterally in a direction at right angles to a line connecting the two shaft centers. This movement of the ring wedges it into the angle of the cones and increases the contact pressure between the cones and the ring in proportion to the load applied. Lubrication is provided by an oil bath in the sealed case.

Various sizes of units are manufactured up to 3 hp at 6:1 ratio, with a maximum ratio of 15:1 available on some of the smaller sizes.

Compound Adjustable Pulleys and Interlocking Dual Pulleys.[8] Compound adjustable pulleys and interlocking dual pulleys are enclosed units. They contain an input and an output shaft mounted in line, each with an adjustable V pulley. A speed-adjustment lever controls the opening in each of these pulleys in such a manner that movement of the lever increasing the opening of one pulley decreases the opening of the second. A countershaft of the interlocking dual-pulley type is mounted parallel to the first two shafts, one of the dual pulleys being belted to the input-shaft pulley and the second belted to the output-shaft pulley (see Fig. 14-72). Thus movement of the speed-variation adjustment lever, causing a tightening of one belt and a loosening of the other, will result in an automatic shift in the openings of the countershaft pulleys to equalize the tension in both belts at the new ratio.

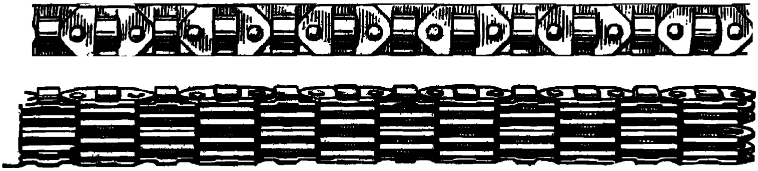

FIG. 14-70. VRD chain.

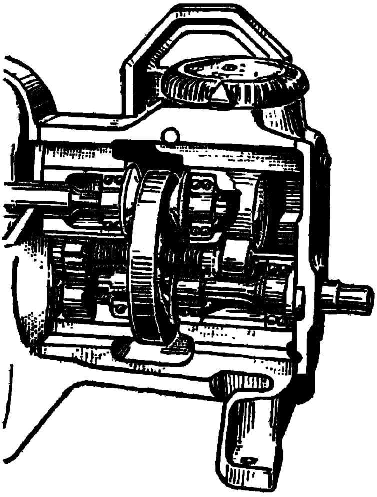

FIG. 14-71. Steel-ring drive.

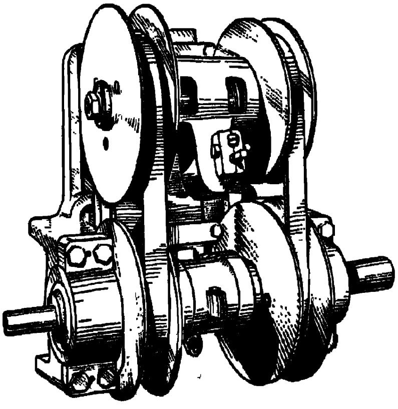

FIG. 14-72. Compound and interlocking dual pulleys, open type shown. Also available with case and cover.

Various sizes of this device are produced, ranging from ¼ hp with 16 :1 ratio, up to 10 hp with 6 :1 ratio.

CONTROLLED DIFFERENTIAL-GEAR SYSTEMS

A differential-gear system alone will not produce a variable-speed drive but must be supplemented by some other variable-speed mechanism to control the relative rotation of the various gears. This is commonly done by adding to the differential gearing a control mechanism based upon the principle of the V belt or chain drive with adjustable cone pulleys. The relative capacity of the combined V drive and differential-gear systems depends upon the ratio range of the V drive and the required ratio range of the differential system.

The advantage of this combination over the use of the V drive alone lies in the fact that only a portion of the power transmitted by the combined system passes through the V-governing drive. Thus the size and weight may be reduced as compared to V drives of equal rating, and units may be constructed to handle larger horsepower requirements. Units may be constructed to operate as low as zero speed or through reverse. In some cases the differential gears are employed to supplement the accuracy of the V drive alone; in others to reduce the effect of ratio change vs. transmitted torque.

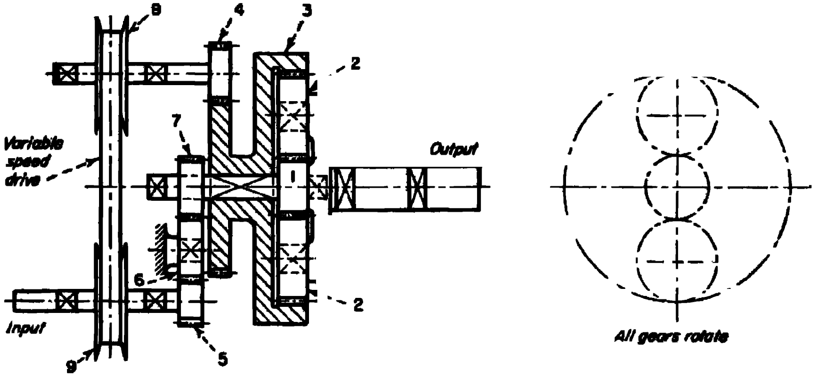

Fig. 14-73. Controlled single differential.

The type of differential-gearing system will vary from one manufacturer to another, some being of the bevel-gear type and others of the planetary-gear type. Some devices employ a double differential-gear system. In the case of the single differential, the torque transmitted through the variable element deviates considerably, depending upon the relative ratio range. With the double-differential type, the torques transmitted through the variable elements do not vary so widely as with the single-differential type.

The gear system shown by Fig. 14-73 is typical of a single-differential device,[9] although numerous other combinations are possible. This uses planet gears (2) located symmetrically about, and meshing with, a pinion (1) which is driven by the input shaft through gears (5, 6, and 7). The inner end of the output shaft has projecting fingers which form the shafts on which the planet gears (2) revolve. The speed of rotation of the output shaft is governed by controlling the relative speed of rotation of a ring gear (3) encompassing the planet gears (2) with respect to the rotation of the input shaft. This control is maintained by a V belt or chain mounted on two adjustable cone pulleys (8 and 9), one of which (9) is on the input shaft, and the other (8) is on a shaft geared through gear (4) to the ring gear.

The single-differential type, in sizes up to 100 hp, may be designed to allow continuous variation from maximum to zero speed or through zero to reverse.

A double-differential-gear system with V belt or chain control mechanism is illustrated in Fig. 14-74. The pinion (15) on the input shaft drives two spider arm gears (1 and 2), which respectively carry the free-turning bevel gears (3 and 4), with them. The relative rotation of the two bevel gears (5 and 6), is controlled by the belt or chain on the two variable V wheels (7 and 8). With pulleys (7 and 8), at the 1:1 position, the bevel gears (5 and 6), rotate at equal speeds, although the other gears (3, 4, 9, and 10), may rotate at sundry speeds dependent upon the ratio of the gears (1 and 2), to pinion (15) and also gears (11 and 12), to gear (14).

With equal ratios in gear sets (1 and 2), to (15), (11 and 12), to (14), and in the two differential-gear sets, equal forward to reverse speed is obtainable by changing the variable-speed V transmission an equal amount or range either side of the mean or 1:1 position, *e.g.*, +400 through 0 to −400 rpm.

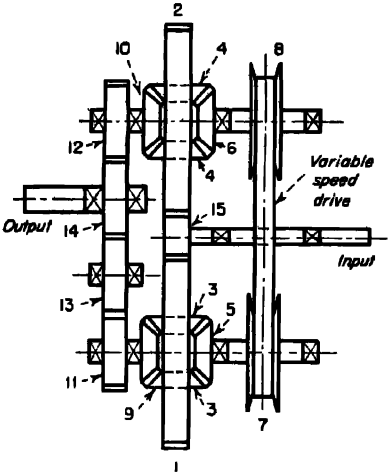

Fig. 14-74. Controlled double differential.

With unequal ratios in gear sets (1 and 2) to (15) and/or (11 and 12) to (14), substantially any desired variable-speed range may be obtained, as follows:

Zero to maximum, *e.g.*, 0 to +800 rpm

Forward through zero to reverse, (unequal values), *e.g.*, +250 through 0 to −75 rpm

Minimum to maximum, *e.g.*, +10 to +600 rpm

GEAR REDUCTION UNITS AND PLANETORQUE REDUCERS

BY J. N. MORRELL

President, E. I. M. Company (Formerly Chief Engineer, Philadelphia Gear Works)

MAJOR DESIGN FEATURES

Many factors require consideration in the design of gear reduction units. It is not the object of this subsection to treat on detail design. However, the engineer should be familiar with the major design features. These are as follows:

Horsepower rating for strength of gear teeth
Horsepower rating for surface durability of gear teeth
Suitability of material for the gears
Practical combination of tooth height, pressure angle, and/or helix angle
Tooth runout, spacing, lead
Relation of center distance and face width to avoid undue concentration of pressure arising from deflection underload
Shaft stresses
Bearing loads and speeds
Foundation and bearing-bolt stresses
Rigidity of housing substantially to maintain shaft position under maximum loads
Thermal horsepower capacity of the unit

The American Gear Manufacturers Association was established during 1917. Within the Association is an engineering body which has formulated standards for the manufacture of gearing and gear reduction units. These standards fully consider the major design features outlined above and are looked upon as the basis for the design, manufacture, and application of the modern gear reduction unit.

Gear reduction units and planetorque reducers are built in many forms, using a wide variety of gears to meet practically every kind of power-transmission and speed-reduction application. Each of the more commonly used speed-reduction units will be treated separately.

PROPER SELECTION

The general advantages of gear reduction units are manifold and must be considered properly to select the correct type for the specific application.

General Advantages. 1. *Power Conservation.* Because of accurate gear design, high-grade workmanship, proper bearings, and adequate lubrication, there is an assurance of minimum loss between applied and delivered power.

2. *Low Maintenance.* If the correct design and power capacity for the requirements are selected and occasional attention is given to the lubrication system, low maintenance costs will result.

3. *Operating Safety.* All gears, bearings, and shafts are enclosed in oiltight, strongly built, cast-iron or steel housings.

4. *Silent Operation.* The entire mechanism is tightly sealed and operates in a bath of oil; therefore noise and vibration are reduced to a minimum.

5. *Space Conservation.* Units are entirely self-contained and extremely compact; therefore they require small space. This also enables them to be installed in out-of-the-way locations.

6. *Adverse Operating Conditions.* Efficient enclosure protects the mechanism from dirt, dust, soot, abrasive substances, moisture, or acid fumes.

7. *Economy.* Units permit the use of high-speed motors direct-connected to low applied speeds. High-speed motors cost less initially.

8. *Life Expectancy.* The life of a unit is practically unlimited if it is properly lubricated and correctly aligned.

9. *Horsepower and Ratios.* Units are available in almost all desired ratios and for all practical power requirements.

10. *Adaptability.* Regardless of the direction between applied and delivered power, a reduction unit can be obtained to fill the requirements.

Efficiency. Efficiency means power conservation. While several types of gear reduction units of identical ratio, identical input speed, and identical horsepower could be selected for a given application, the efficiency of the drive may vary from 50 to 96 per cent. Table 14-94 shows anticipated efficiencies of the various types of speed-reduction units.

Table 14-94

Type of reduction unit	Ratio	Stage of reduction	Efficiency, per cent
Herringbone and helical	Up to 10:1	Single	98
	10:1–60:1	Double	97
	60:1–360:1	Triple	96
Spiral bevel and hypoid	Up to 6:1	Single	98
Spiral-bevel herringbone and spiral-bevel helical	6:1–40:1	Double	96
	20:1–240:1	Triple	95
Gearmotors	4:1–10:1	Single	98
	10:1–20:1	Double	97
	20:1–100:1	Triple	96
Worm gear	3½:1–100:1	Single	*
	100:1–10000:1	Double	†

* Efficiency of single-reduction units is 100 − (ratio/2).
† Efficiency of double-reduction units is 100 − (ratio of first reduction/2) × 100 − (ratio of second reduction/2).

Space conservation also means efficiency. Gear reduction units, being extremely compact, comprising types built with various relations of input shaft to output shaft, permit remarkable adaptability. The unit that satisfies the requirements of relation between applied and delivered power, both as to location and rotation of input and output shafts, should be selected. Then the most efficient of the several types of drives available should be chosen.

All other features listed under general advantages should automatically be realized.

Before a gear reduction unit can be selected for any given application, the equivalent horsepower must first be computed by multiplying the specified or actual horsepower by a "service factor" for the particular class of service for which the gear reducer is to be used. It is necessary for low maintenance, operating safety, and reasonable life expectancy that the gear reduction unit selected have a capacity equal

Table 14-95. Service Factors

Character of load on driven machine	Source of power								
	Electric motor drive			Multicylinder gas or steam engine or turbine			Single-cylinder gas engine		
	Intermittent, 3 hr per day	8–10 hr per day	24 hr per day	Intermittent, 8 hr per day	8–10 hr per day	24 hr per day	Intermittent, 3 hr per day	8–10 hr per day	24 hr per day
Uniform	0.8	1.0	1.25	1.0	1.25	1.5	1.25	1.5	1.75
Moderate shock	1.0	1.25	1.5	1.25	1.5	1.75	1.5	1.75	2.0
Heavy shock	1.5	1.75	2.0	1.75	2.0	2.25	2.0	2.25	2.5

to or in excess of the equivalent horsepower. The recommended service factors for various load characteristics and duration of service are given in Table 14-95.

Certain typical and more common speed-reduction-unit applications are classified in Table 14-96 into the three commonly recognized load classifications according to the nature of the load and the usual duty cycle. No attempt has been made to include all possible applications of gear reduction units, but a sufficient number and variety have been covered to serve as a guide for proper application classification.

Table 14-96. Load Classification

Uniform load		Moderate-shock load		Heavy-shock load
Agitators, liquid and semiliquid	Fans, centrifugal and propeller	Beaters, pulp	Feeders, apron, belt, screw,	Compressors, single- or two-cylinder
		Blowers, lobe		
Blowers, centrifugal or vane	Feeders, disk type	Compressors, centrifugal or rotary reciprocating (three or more cylinders)		Conveyors, reciprocating
	Generators		Hoists, reversing Skip	
Conveyors (uniformly loaded or fed) Apron Assembly Belt Oven Screw	Line shafts, light duty		Kilns, cement Lime	Crushers, ore Stone
	Mixers, liquid Semiliquid	Conveyors, heavy duty Apron Belt Live roll Screw	Mills, ball Pebble	Dredge cutterhead
	Pumps centrifugal Geared Rotary		Mixers, dough	Feeders, reciprocating
Can-filling machines				
		Drawbench	Pumps, reciprocating (three or more cylinders)	Jordans
Elevators, bucket (uniformly loaded or fed) Centrifugal discharge Gravity discharge Continuous bucket	Screens, traveling, water, intake	Dryers, rotary		Mills, hammer Pug Rod Rubber
	Stokers	Elevators, heavy-duty bucket Freight	Screens, rotary, gravel or stone	Pumps, reciprocating (single or two cylinders)
	Textile machinery			
		Fans, mine Induced draft	Stock chests	
			Washers, reversing	
			Wire-drawing machines	

While Table 14-96 is a suitable application-classification guide, consideration must be given applications such as the following:

High Energy Loads. Extreme repetitive shock and those applications where exceedingly high energy loads must be absorbed, as when stalling, require special consideration and are, therefore, not covered by service factors given in Table 14-95.

High Momentary Loads. Where the actual maximum momentary or starting load exceeds 200 per cent of normal, the equivalent horsepower is obtained by dividing the maximum momentary load by 2. If this value exceeds the value for equivalent horsepower obtained from a consideration of the service and duty, it must be used in selecting the size of reducer.

Brakes. Where motors are equipped with brakes and the torque rating of the brake exceeds the rating of the motor, the rating of the brake dictates the selection of the gear reduction unit.

High Input Speed. Gear reduction units of the types listed in Table 14-94 are suitable for application where the input speed does not exceed 3,600 rpm and where the pitch-line velocity of the gearing or the rubbing velocity of the worm in worm gearing is not in excess of 4,000 fpm. Special consideration must be given drives where these values are exceeded.

Speed-increasing Units. The single-stage reduction unit of the several types within Table 14-94 may be used for speed-increasing purposes as well as speed-reducing units. However, the output speed in such instances must be limited to 3,600 rpm, and the pitch-line velocity of the gearing or the worm rubbing velocity may be limited to 4,000 fpm. When higher output speeds and higher pitch-line velocity are required, these need special consideration.

Overhung Loads. Where the gear reduction unit is not directly coupled to the motor or other high-speed prime mover and also where the gear reduction unit is not coupled directly to the load, special consideration must be given the resulting overhung loads. A gear, sprocket, sheave, or pulley may be mounted on either or both input and output shafts. It is advisable with such applications to provide an outboard bearing. However, if structural restrictions interfere, the manufacturer should be advised of the pitch radius of the gear, sprocket, sheave, or pulley and the load to be transmitted by the gear, sprocket, sheave, or pulley so that full consideration may be given the bearings of the unit.

WHAT CARE TO GIVE THE GEAR REDUCTION UNIT

Proper selection of the gear reduction unit ensures low maintenance. But, this does not mean "no maintenance."

Prime consideration must be given alignment of the equipment upon installation. Gear reduction units are frequently supplied coupled with the driving motor or other prime mover and mounted on a common bedplate. Such assembly ensures proper alignment and checking of alignment in the machine shop before delivery to the field.

Upon field installation the bedplate assembly must be properly aligned and coupled to the driven machine. Much damage not immediately noticeable has occurred when misalignment has been initially present.

Observation of coupling action when first operating a drive provides a simple reasonable check of alignment. Misalignment has been the cause of coupling failure, shaft breakage, and bearing replacements, all of which can be avoided by good alignment initially.

After initial installation and alignment, the gear reduction unit should be filled with lubricant specified by the manufacturer. All gear reduction units built in accordance with the American Gear Manufacturers Association standards carry a name plate bearing full instructions for the selection of the correct lubricant.

After a gear unit is first installed and filled with oil, the original oil should be changed or filtered at the end of 2 weeks. The casing should be thoroughly flushed out with a light flushing oil. After this, change of oil every 6 months should be sufficient unless there are unusual temperature conditions combined with intermittent high loads, where the temperature of the case rises rapidly and then cools off quickly. Sweating of the casing walls occurs under these conditions, thus contaminating the oil and forming sludge. Should the unit be subject to such conditions or to wet or exceptionally moist atmosphere, it is advisable to change oil at 90-day intervals or more frequently.

Greased Bearings. Most bearings are lubricated by splash through the medium of the revolving gears. Some bearings, however, are grease-lubricated. These bearings are normally provided with grease fittings and should be checked at regular intervals of 90 days.

Venting of Units. Gear reduction units are usually provided with "breathers." The breathers should be examined not less than every 90 days to ensure efficient operation of the gear reduction unit. Where equipment is subject to excessive dirt, dust, soot, abrasive substances, moisture, or acid fumes, more frequent inspection of the breathers is warranted.

Forced-feed Lubrication. Some gear reduction units are equipped with a force-feed system of lubrication. Driver of the pump may be the gear reduction unit or a separate motor. In either event, daily checking of the pump drive and the filter which is normally a part of the system is necessary. Upon starting up after idle periods, particular attention should be given the pump.

Lubrication of Gear Reduction Units. The American Gear Manufacturers Association standard specification for lubrication of enclosed gear drives is applicable to the types listed in Table 14-94.

The specifications apply only when the gears and enclosures are designed and rated in accordance with American Gear Manufacturers Association standards. The ambient-temperature range for which they apply is from 0 to 150°F. Gear drives operated outside this range or those operating in extremely humid or chemical-laden atmosphere should be referred to the manufacturer or lubricant supplier for his recommendation.

The areas of contact on gear teeth are relatively small, and the unit pressures produced in transmitting the load are relatively high. It is, therefore, essential to provide a film of lubricant of sufficient strength to withstand the localized pressure during the period of contact. The peripheral speed of the gears governs the period of tooth contact and determines the length of time the film must withstand the pressure. When speeds are high, the time is very short, and the loads are usually light. As a result, an oil of comparatively low viscosity should be used. When speeds are low and the loads heavy, the contact time is considerably longer, and an oil of higher viscosity should be used.

Table 14-97

AGMA lubricant No.	Viscosity range SUV sec	
	At 100°F	At 210°F
1	180–240	
2	280–360	
3	490–700	
4	700–1,000	
5		80–105
6		105–125
7		125–150
7 comp.*		125–150
8		150–190
8 comp.*		150–190

* The oils marked "comp." are those compounded with 3 to 10 per cent acidless tallow or other suitable animal fat.

Temperature. The ambient temperature has considerable bearing on the viscosity of oil to be used. The viscosity of mineral oil varies inversely with the temperature, which makes it desirable to use an oil of heavier grade at high ambient temperature. Also, for low temperatures an oil must be selected that has a pour point lower than the minimum temperature expected for the application.

Type of Oil. Lubricating oils should be high-grade, high-quality, well-refined petroleum oil. They must not be corrosive to the gear, or to ball, roller, or sleeve bearings. They must be neutral in reaction, free from grit or abrasive, and have good defoaming properties. For high operating temperatures they must have good resistance to oxidation.

Viscosity. The viscosity range for the various American Gear Manufacturers Associations lubricants is shown in Table 14-97.

Table 14-98 shows the grade of oil to use for drives of all types except those employing worm gears. The latter group is covered by Table 14-99.

Table 14-98. Recommended Lubricants for Enclosed Units of All Types Except Worm Gears

Type of unit	Size of units	Ambient temperature, deg F		
		0–40, use AGMA No.	41–100, use AGMA No.	101–150, use AGMA No.
Parallel-shaft units	Low-speed centers up to 20 in.	2	4	5
	Low-speed centers over 20 in.	3	5	6
Planetary-gear units	OD of housing up to 16 in.	2	3	4
	OD of housing over 16 in.	3	4	5
Gearmotors	All sizes	2	4	5
Spiral or straight bevel-gear units	Cone distance up to 12 in.	2	4	5
	Cone distance over 12 in.	3	5	6
High-speed units	All sizes	1	2	3

Table 14-99. Recommended Lubricants for Enclosed Worm-gear Units Only

Service and worm speed	Ambient temperature, deg F		
	0–40, use AGMA No.	41–90, use AGMA No.	91–120, use AGMA No.
Intermittent operation, all worm speeds*	5	5	7 comp.
Continuous operation, worm speeds below 600 rpm	7 comp. diluted†	8 comp.	8 comp.
Continuous operation, worm speeds 600 rpm and over	7 comp. diluted†	7 comp.	8 comp.

* Where period of operation is insufficient to produce any appreciable rise in oil-bath temperature.

† Diluted AGMA No. 7 comp. oil should be diluted with a lighter oil, preferably not exceeding 500 sec viscosity at 100°F, until the desired fluidity is obtained. The lubricant used for dilution should be of the same basic crude as that of the recommended oil. The lubricant supplier should be consulted if there is any doubt.

Antifriction Bearings. A good mineral grease should be used for antifriction bearings. Choice of lime-soap grease or soda-soap grease is recommended dependent upon bearing temperatures.

Lime-soap greases are suitable for bearing temperatures of −20 to +45°C. Soda-soap greases have a higher drop point and, therefore, can be used between −20 and +70°C.

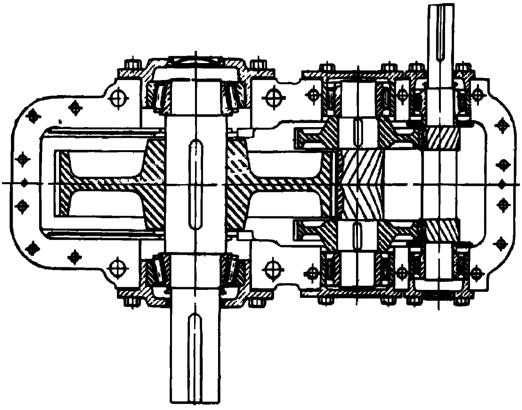

FIG. 14-75. Sectional view of double-reduction herringbone-gear unit.

Ball and roller bearings require only a small amount of lubricant, and lubrication intervals are generally long. However, lubricants must always be present in the bearings; otherwise their life will be affected.

Thermal Capacity. Since most oils lose their lubricating quality at temperatures of approximately 200°F, it is standard practice to limit the temperature of the oil in the sump to 200°F. Normal allowable temperature rise is 90°F above ambient but not to exceed an oil-sump temperature of 200°F.

The heat generated by the gear reduction drives must, therefore, be radiated by the casing enclosing the gearing. Relatively large radiating areas must be provided, particularly where low-efficiency drives are used.

There are instances where the radiating surface of the gear reduction unit will limit the rating of the drive. It then becomes the thermal rating. Where the mechanical rating exceeds the thermal rating, the selected gear reduction drive may be used provided that direct cooling by means of water-cooling coils or oil cooling by heat exchanger is employed.

HERRINGBONE-GEAR REDUCTION UNITS

Herringbone-gear reduction units operate quietly, produce uniform torque, and transmit smooth, even flow of power free from vibration or pulsation.

The units, normally, are for floor mounting with parallel shafts. Input and output shafts may extend on same or opposite sides. Units also may be arranged with one shaft above the other or for wall mounting where conditions require this.

In these units, the gears are located symmetrically, not offset or staggered. The symmetrical arrangement of the gears permits the use of two standard bearings of identical size on each shaft, the equidistant spacing resulting in equal loading of the bearings.

The gears may be of the continuous herringbone type, generally known as the "Sykes form," or opposed single helical gears.

A sectional view of a double-reduction herringbone-gear unit is shown by Fig. 14-75. It indicates the symmetrical arrangement of gears and bearings.

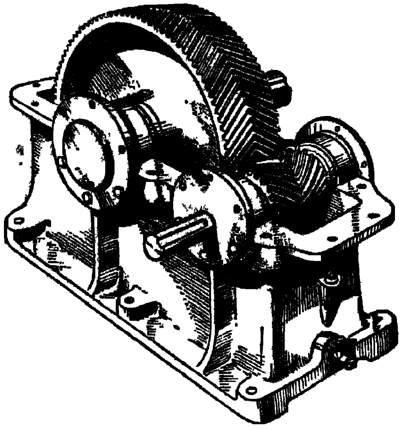

Fig. 14-76. Single-reduction herringbone-gear unit.

Figures 14-76, 14-77, and 14-78 show, respectively, single-reduction, double-reduction, and triple-reduction units with covers removed.

A double-reduction herringbone unit rated 50 hp at 1,150 rpm, ratio 45.8:1, is shown in Fig. 14-79 driving a chemical-plant dryer.

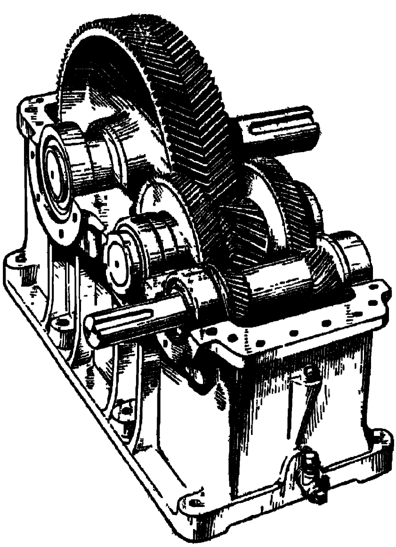

Fig. 14-77. Double-reduction herringbone-gear unit.

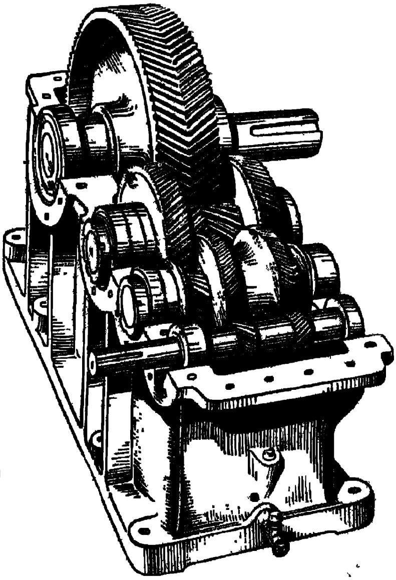

Fig. 14-78. Triple-reduction herringbone-gear unit.

High-speed Herringbone-gear Reduction Unit. For applications where shaft speeds and pitch-line velocity exceed the limits stated, high-speed herringbone units are available. These units are equipped with special force-feed lubrication of gears and a water-cooled heat exchanger to dissipate the heat generated in high-speed operation. Special bearings are employed Noise and vibration are held to a minimum through the balancing of the gears combined with rigid bearing mounting. Such units are used for turbine drives, to pumps or other machinery, and for speed increasers from low-speed motors or engines to high-speed pumps, fans, etc.

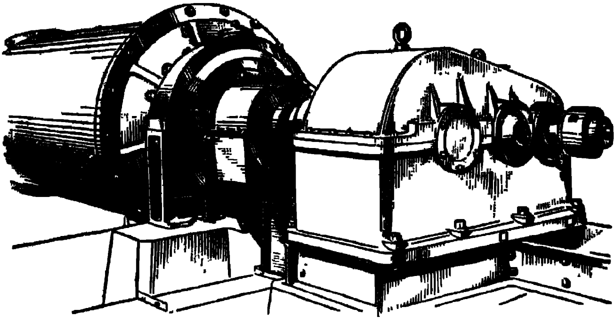

FIG. 14-79. Typical installation of double-reduction herringbone-gear unit.

Figure 14-80 shows a high-speed herringbone unit complete with pump, filter, cooler, and piping.

Helical-gear Reduction Units. Helical-gear reduction units are normally built in the same arrangement and the same housing employed for herringbone-gear reduction units. The features, service factors, and application data are the same as for herringbone-gear reduction units.

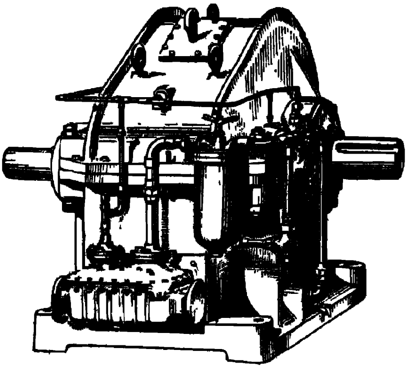

FIG. 14-80. High-speed herringbone-gear unit equipped with oil pump, filter, and cooler.

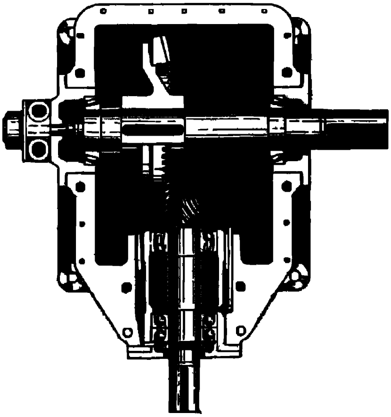

FIG. 14-81. Sectional view of spiral-bevel-gear reduction unit.

An additional load is imposed on the bearings owing to the thrust action of the single helical gears and must be considered in bearing selections.

Spiral-bevel-gear Reduction Units. The parallel-shaft speed reducer of the herringbone-gear and helical-gear type combine simplicity of design with comparatively low cost. These units are utilized in many power-transmission applications. However, when space is limited, it is often necessary to take advantage of the compactness offered by the right-angle drive.

The right-angle drive has certain decided advantages when compared to the parallel-shaft drive, and where the low-speed shaft must be vertical, the use of the right-angle drive is preferable.

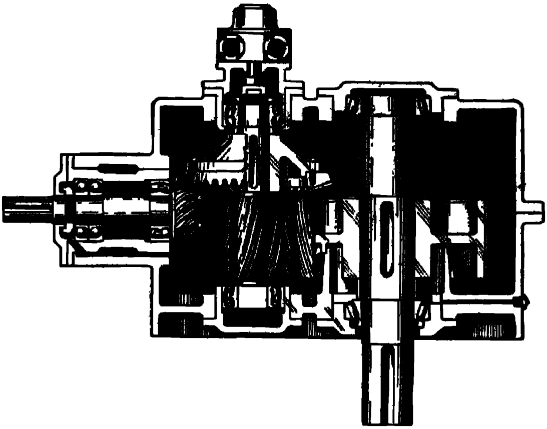

Fig. 14-82. Sectional view of vertical spiral-bevel helical-gear unit.

For single-reduction units, only spiral bevel gears are used. For double and triple reductions, helical gears or herringbone gears are used.

Sectional view of horizontal spiral-bevel-gear reduction unit is shown by Fig. 14-81. Vertical spiral-bevel helical-gear double-reduction unit, sectional view, is shown by Fig. 14-82. Sectional view of horizontal spiral-bevel helical-gear triple-reduction unit is shown by Fig. 14-83.

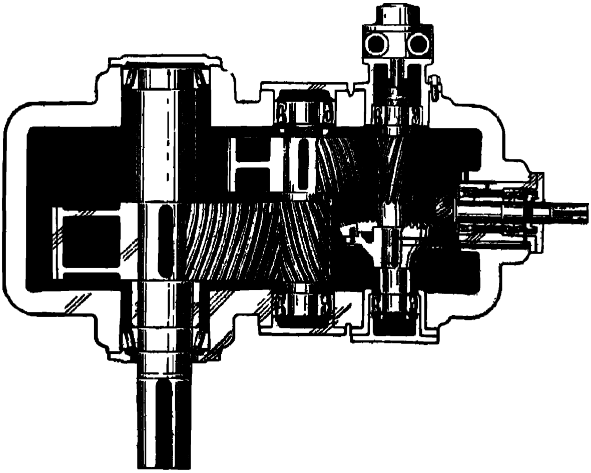

Fig. 14-83. Sectional view of horizontal spiral-bevel helical-gear unit.

Arrangement of Shafts and Rotations. When purchasing spiral-bevel or combination right-angle drives, the hand of assembly must be specified for horizontal units, and the direction or rotation of both input and output shafts must be given for all

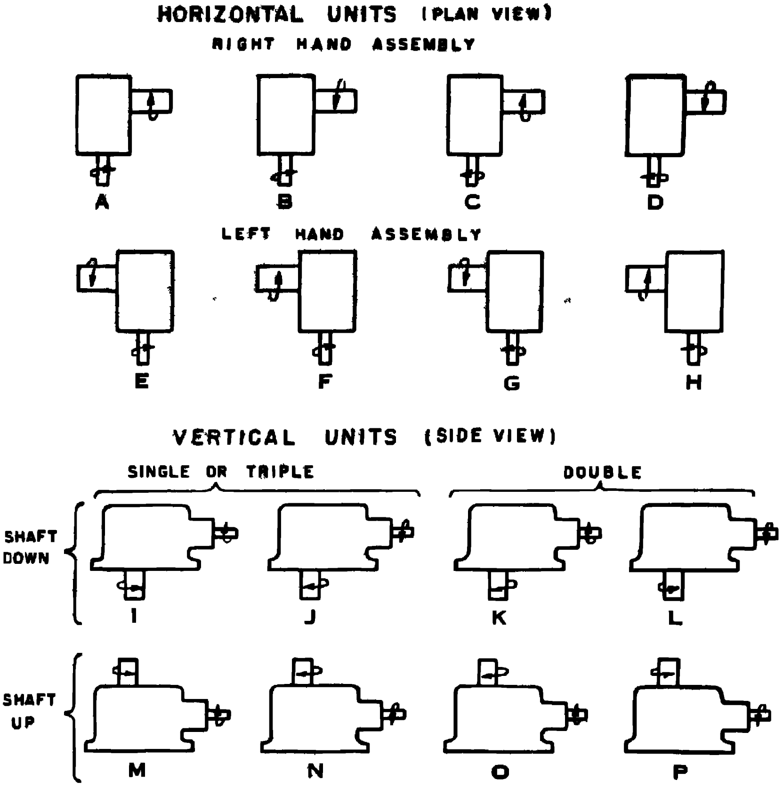

Fig. 14-84. Proper shaft arrangement and rotation for spiral-bevel and combination right-angle drives.

units. In most instances, the direction of rotation of the output shaft only is fixed, and the input shaft is driven by a motor which may rotate in either direction. Proper shaft arrangement and rotation are shown by Fig. 14-84.

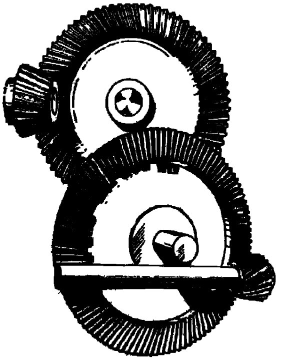

Fig. 14-85. Hypoid gears.

Hypoid-gear Reduction Units. General features of the hypoid reduction unit are those of the spiral-bevel-gear reduction unit. However, the hypoid gear has the additional advantage over the spiral bevel gear in that it permits transmission of power between offset shafts.

Hypoid-gear reduction units are designed for transmitting power between shafts at practically any angle. These drives should be used for speeds in excess of 800-fpm pitch-line velocity where smooth and quiet operation, together with minimum size, is required. Continuous pitch-line contact of hypoid gears makes it practical to obtain superior performance with a smaller number of teeth in the pinion than is possible with straight bevel gears.

The shaft offsets for all ratios above 3:1 should not exceed 20 per cent of the diameter of the gear. For 1:1 ratio, the maximum offset should not exceed 30 per cent of the diameter of the gear. Ratios between miter gears and 3:1 ratio should have proportionate shaft offsets (see Fig. 14-85).

GEARMOTORS

Gearmotors are built in many forms, using a wide variety of gears to meet practically every kind of power-transmission and speed-reduction application. Of the several types of gearing, the planetary finds extensive use for certain drives. Nonplanetary gearing is also employed. Gearmotors may be of the parallel- or concentric-shaft types.

Spur, helical, and, in some unusual cases, herringbone gears are used for both planetary and nonplanetary systems.

The simple planetary system consists of a sun pinion driving several idler gears mounted in a spider inside a fixed internal ring gear meshing with the idlers. The output shaft is part of the idler spider. The three-idler system is the one most widely used. All rotating elements are normally mounted on antifriction bearings and contained in a single enclosure.

Gearmotors are available in both horizontal and vertical types, with the motor built in or bolted on. Motors are standard open type, totally enclosed, fan cooled, totally enclosed nonventilated, explosionproof, or with other variations, both electrical and mechanical.

Figure 14-86 shows the vertical type of two-stage reduction. Figure 14-87 shows horizontal-type two-stage reduction with built-in motor. Figure 14-88 shows nonplanetary type three-stage reduction-gear motor with bolted-on motor.

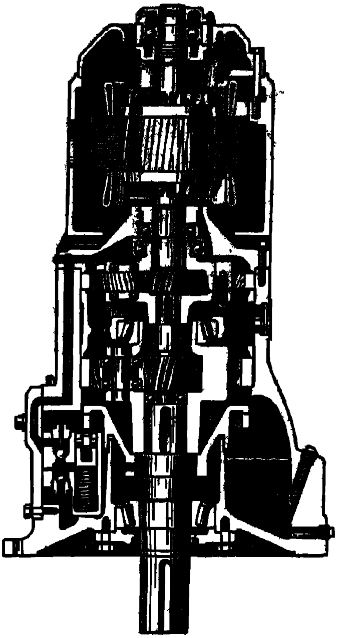

Fig. 14-86. Vertical two-stage gearmotor.

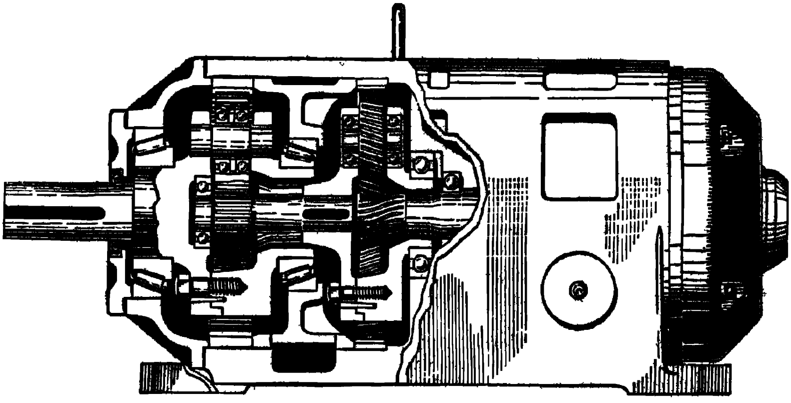

Fig. 14-87. Horizontal two-stage gearmotor.

Gearmotors fall within three general classifications of the American Gear Manufacturers Association. These are as follows:

Class I. For steady loads not exceeding normal rating of motor and 8-hr-per-day service; moderate shock loads where service is intermittent

Class II. For steady loads not exceeding normal rating of motor and 24 hr per day; moderate shock loads for 8 hr per day

Class III. For moderate shock loads for 24 hr per day; heavy shock loads for 8 hr per day

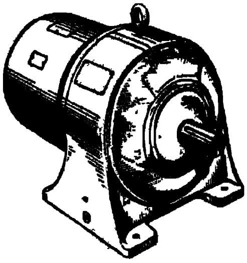

FIG. 14-88. Three-stage reduction-gear motor with bolted-on motor.

Certain typical and more common gearmotor applications have been classified in Table 14-100 according to the nature of the load and the usual duty cycle into the three commonly recognized classifications. No attempt has been made to include all possible applications of gearmotors, but a sufficient number and variety have been covered to serve as a guide for proper application classification.

Extreme repetitive shock and those applications where exceedingly high energy loads must be absorbed, as when stalling, require special consideration and are, therefore, not covered by classes I, II, or III. These include gearmotors for application to runout tables, sheet catchers, etc. Certain types of machines equipped with flywheel on the output shaft may come under this classification and should be checked to determine that the flywheel is adequate to absorb the peak loads. Flywheels are not to be used on the input shaft of gearmotors.

Where motors are equipped with brakes and the torque rating of the brake exceeds the rating of the motor, the rating of the brake dictates the selection of the gear.

Planetorque Reducers. Gearmotors are available with a built-in overload protective device known as "Planetorque." This protective device, operable in either direction of shaft rotation, is ideal for applications like stoker drives, conveyor drives, mixers, roll drivers, etc., where overloads would stall and seriously damage expensive machinery.

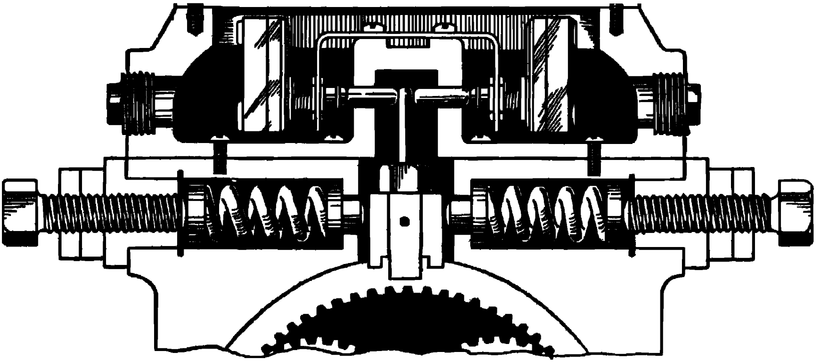

FIG. 14-89. Sectional view of the Planetorque device.

A sectional view showing internal construction of the Planetorque device is shown in Fig. 14-89. Figure 14-90 shows a horizontal gearmotor equipped with Planetorque device.

Figure 14-89 shows the internal ring gear of the planetary set arranged in the housing so that it may rotate. However, the ring gear is restrained from rotating by the compression springs on either side of the projection fastened to the periphery of the ring gear.

Spring loading may be varied by means of the adjusting screw.

Thus, when the setting of the spring has been reached owing to overloading of the drive, the internal gear tends to rotate, compressing the spring and actuating the switch in the enclosure directly above the springs. Motor control circuit is automatically broken, and the equipment remains inactive until the cause of the overload has been determined and corrected.

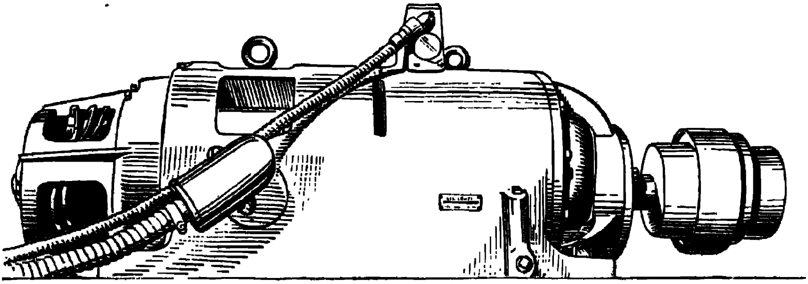

FIG. 14-90. Horizontal gearmotor equipped with Planetorque device.

On removal of the excessive load, equipment can be started without resetting the switch.

This device offers many advantages over other protective devices such as shear pin couplings, thermal overload relays, etc.

WORM-GEAR REDUCTION UNITS

Although worm gearing has been employed since the early centuries, it has been only within the last 30 years that the most rapid progress has been achieved. This has been due, primarily, to development of equipment for production of modern designs of exceptionally high efficiency.

Worm-gear reduction units transmit power by continuous shockless action. Three or more teeth are in contact at all times, giving an even flow of torque and uniform angular velocity, eliminating vibration, pulsation, and chatter.

The worm-gear reduction unit is a compact right-angle drive that provides larger ratios of speed reduction in a single stage than available in other types of gear reduction units.

Worm gears are normally produced from a special gear bronze, the worm normally from an alloy steel, the threads being carburized, hardened, tempered, machine ground, and polished. The bronze gear teeth necessarily maintain their correct form owing to the regenerating action of the hardened-steel worm, which retains its original shape throughout years of wear. A worm-gear reduction unit actually improves with service. This fact is peculiar to worm gearing and contributes to its recognized long life.

Assuming proper lubrication, worm-gear drives operate with little attention even under the most adverse conditions. The small number of moving parts in a worm-gear drive tend to safety and ease of maintenance.

Figure 14-91 shows the section through the worm and worm-gear shafts of a drive where the worm is placed below the worm gear.

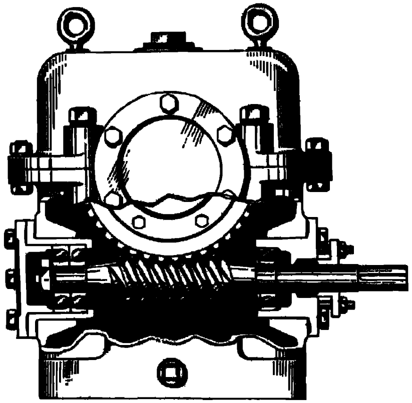

Fig. 14-91. Section through worm-gear unit with worm below worm gear.

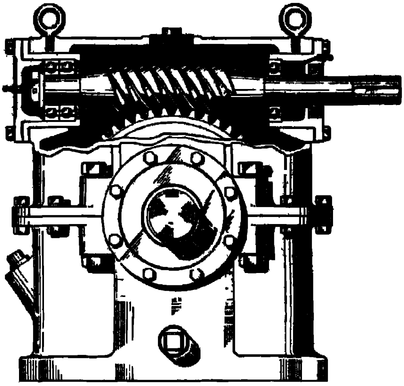

Fig. 14-92. Section through worm-gear unit with worm above worm gear.

Figure 14-92 shows a section through worm of a drive where the worm is assembled above the worm gear.

Figures 14-93 and 14-94 show sections through the gear shaft of vertical units, Fig. 14-93 showing the shaft projecting downward, Figure 14-94, with the shaft projecting upward.

Figure 14-95 shows a sectional view of a two-stage or double-reduction worm-gear unit.

Worm-gear reduction units are normally applied in accordance with the following recommended classifications of the American Gear Manufacturers Association:

Class I—Normal 8- to 10-hr service, free from recurrent shock loads (*i.e.*, shock loads that recur at approximately even and frequent intervals). The mechanical ratings of the manufacturer are to be applied directly in this classification, provided only that the thermal rating is not exceeded.

Class II— Eight to ten hours' service where recurrent shock loading is encountered, or 24-hr service where no shock loading is experienced. The mechanical ratings of the manufacturer must be reduced by dividing by 1.2 for this service. The thermal rating must not be exceeded.

Class III—Twenty-four hours' shock-load service. The mechanical rating must be reduced by dividing by 1,333 for this service, and the thermal rating must not be exceeded.

Class IV—Intermittent service where the maximum cycle of operation calls for not more than 15 min running in a 2-hr period. The mechanical rating may be divided by 0.7 to obtain a rating for the service classification. The thermal rating may be ignored.

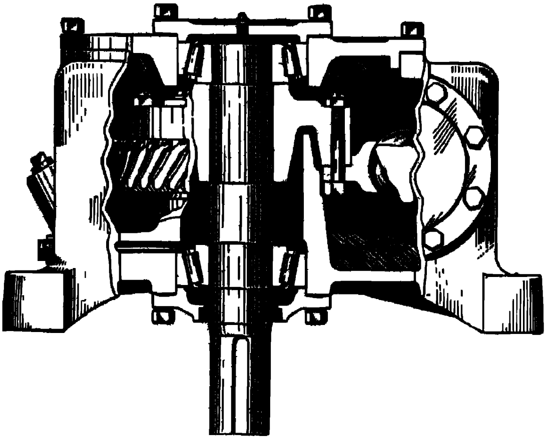

FIG. 14-93. Section through vertical worm-gear unit with driven shaft downward.

Class V—Low-speed service (where worm speed is less than 100 rpm) will require output-torque ratings in inch-pounds, independent of the nature or duration of the loads.

Worm-gear reduction units are rated mechanically and thermally by all manufacturers. The mechanical rating is based on the wear resistance of the gear teeth. The worm-gear tooth form is such that the gear teeth are under a crushing rather than a bending load, and for this reason extremely high momentary and shock loads damaging to many forms of gearing can be successfully withstood. The beam or structural strength of the tooth is considerably in excess of the wear-resistant rating.

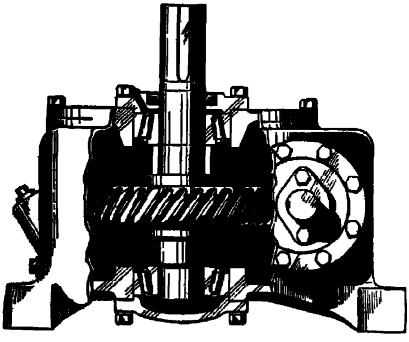

FIG. 14-94. Section through vertical worm-gear unit with driven shaft upward.

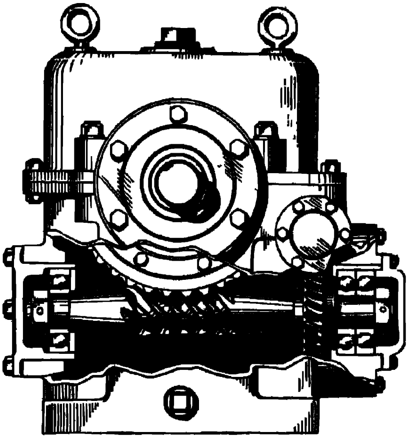

FIG. 14-95. Section through double-reduction worm-gear unit.

The thermal rating indicates the amount of power that can be delivered through the unit continuously without overheating the unit. This rating is based on the radiating area of the housing and varies only with the efficiency of the unit which in turn is dependent on the ratio of reduction. Thermal ratings, therefore, are independent of service classification.

For continuous service, the unit must be selected according to the lesser of the two ratings. If the thermal rating is lower than the mechanical rating, the unit must be selected on the thermal rating. However, for class IV service, the thermal rating may be neglected, for the service classification does not permit sufficient time for the unit to heat up.

Fan Cooling. The use of coils carrying circulating water to reduce temperature of the oil bath is employed to increase the thermal capacity of worm-gear reduction units. But water usage in such volume to be adequate for cooling is not economical in some plants. Some applications utilize a circulating system for the lubricant and a heat exchanger. But this is costly. To improve upon these methods and to increase the over-all efficiency of worm-gear reduction units, the fan-cooled unit has been developed.

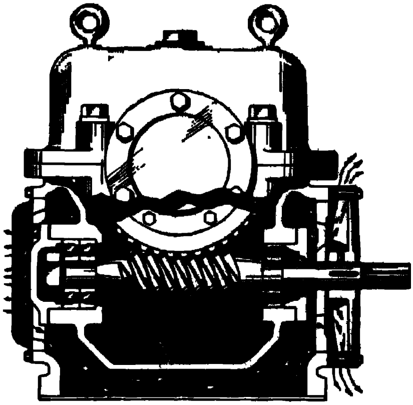

Fig. 14-96. Fan-cooled worm-gear reduction unit.

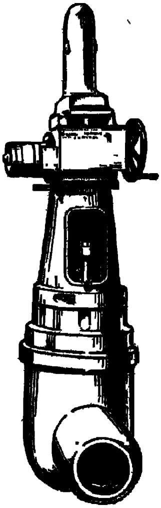

Fig. 14-97. Gear-unit valve control mounted on gate valve.

Conventional worm-gear reduction units are provided with dual walls. The ribbed inner housing provides a large heat-exchange surface. The outer housing wall which carries gear and shaft loads is kept cool, since it does not contact the oil bath. Thus, distortion due to temperature changes is eliminated, and bearings, shaft, and gears are maintained in proper alignment.

A fan is mounted on the worm shaft. This fan draws air from the opposite end of worm shaft over the ribbed inner housing reducing the temperature of the oil bath to approximately 200°F. Temperature of the drive is thus held to a limit permitting satisfactory lubrication and accordingly increasing capacity over drive without such cooling feature.

As an example, suppose the requirements were for 20-hp at 1,750 rpm, ratio 4.667:1. A worm-gear unit of 6.75 in. center distance would be needed to satisfy this requirement when considering the standard type. The fan-cooled unit of 4.75 in. center distance would amply satisfy these requirements.

Figure 14-96 illustrates the fan-cooled worm-gear reduction unit showing a view through the worm shaft.

Electric Operators for Valves. The characteristics of electric operators for valves parallel, in so far as the gear reduction unit is concerned, the conventional worm-gear reduction unit. While valve operators are subject to momentary peak loads at the time of shutting off the valve or cracking the seat of the valve, the loading at other times is negligible involving usually the weight of the moving parts and friction only.

The gear reduction unit is equipped with a flange-mounted motor rated in pounds-feet torque and of short-duty cycle. Valve-operator motors are infrequently rated in horsepower.

The gear reduction box is also equipped with switches to control the opening and closing travel of the valve, as well as switches to provide actuation of indicating-light system and interlocking system where necessary.

Housed in the gear reduction unit is the valve yoke nut which raises or lowers the stem, opening or closing the valve. Valves of the nonrising-stem type are also driven by the yoke nut within the valve-control gearbox, but instead of being threaded to mate with the valve stem, the yoke nut is bored and keywayed to fit the stem of the nonrising-stem valve.

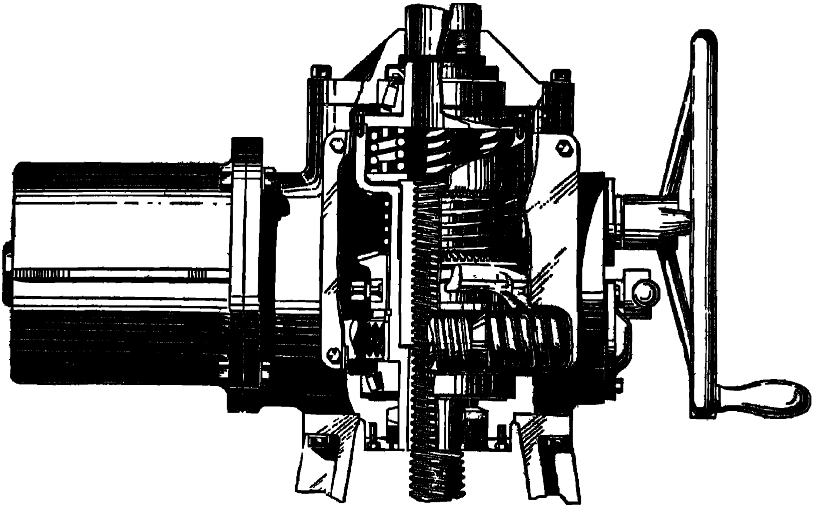

FIG. 14-98. Sectional view of valve operator.

Figure 14-97 shows valve control mounted on a gate valve. Figure 14-98 shows a sectional view of what is termed the operator.

A handwheel is provided for manual operation. The handwheel does not revolve during motor operation. During hand operation, the motor is mechanically disengaged and does not rotate. A lever is provided to change from motor to hand operation, but the unit returns automatically to motor operation.

A spring compensator is provided which permits the valve stem to expand or contract with temperature changes but ensures tight closure of the valve regardless of temperature variations.

A torque seating switch ensures tight valve closure without damage to the valve or the mechanism. This switch may be adjusted to the desired seating thrust and can be varied over a wide range. The torque switch also protects the valve in the event of an obstruction being encountered during the closing operation.

What to Do When Trouble Occurs. Heating does not mean trouble. Overheating does mean trouble. If the temperature of the oil-bath lubricant is 200°F, this may be considered normal for most gear reduction units. When this temperature is exceeded, a search should be made for the cause.

Naturally there are spot temperatures, such as the teeth at point of mesh, that are higher than 200°F. But if the oil in the sump is in the neighborhood of 200°F, the unit can be considered operating normally.

Table 14-101. Trouble Chart

Trouble	*What to inspect*
Heating	Is unit overloaded?
	Has recommended oil level been exceeded, or is level too low?
	Are couplings in alignment?
	Have bearings been properly adjusted?
	Are oil seals or stuffing boxes the cause?
	Perhaps breathers are not clean.
	Is oil clean, or is sludge content high?
	Have you cleaned oil filter?
	Is oil pump functioning?
Shaft failure	Check alignment. Most shafts fail owing to misalignment.
	Some troubles are caused by use of rigid couplings.
	Is overhung load beyond capacity of unit?
	Is unit subject to high energy loads or extreme repetitive shocks not previously considered?
Bearing	Rust formation due to entrance of water or humidity.
	Unsuitable lubricant.
	Abnormal loading causing excessive deflection results in flaking, cracks, fractures.
	Improper adjustment causes abnormal loading if bearings are pinched or abnormal gear wear if bearings are too free, dependent upon type of bearing.
	Lack of lubrication.
Oil leakage	Check oil seals and replace if worn.
	Check stuffing boxes and adjust or replace packing.
	Check tightness of drain, level, and other plugs or fittings.
Wear	Backlash may be insufficient.
	Misalignment due to worn bearings.
	Incorrect lubrication.
	Insufficient lubrication.
	Lubricant carrying foreign matter, viz., abrasive dirt or particles of metal worn from teeth.
	Excessive temperature.
	Excessive speeds.
	Excessive loads.
Noise	Bad alignment.
	Loose or worn bearings.
	Insufficient lubrication.
	Lack of lubrication.
	Excessive lubrication.

While gear reduction units are suitable for momentary overloading up to 100 per cent of their normal rating, there have been instances where this permissible momentary overloading has been exceeded. The user frequently overloads the unit up to 100 per cent or more for a period of from several minutes to perhaps an hour or more daily. Such cases of overloading cause excessive heating during the period of overload. And this, while seldom resulting in breakage immediately, does cause more rapid wear of the gear teeth and in time may be the cause of bearing or shaft breakage.

Improper lubrication certainly covers a large percentage of gear reduction-unit failures. Too frequently units are started up without any lubricant at all. Sometimes the belief seems to be that a higher oil level than called for is better lubrication. This usually results in more of the input power going into churning of the oil creating excessive temperatures with detrimental results to the bearings and gearing. Likewise, insufficient lubricant effects the same results.

Almost 98 per cent of gear reduction unit failures have been attributable to misalignment, improper lubrication, and misapplication. Therefore, if these major points are recognized, the modern gear reduction unit will perform satisfactorily.

AIRFLEX CLUTCHES

BY THE DIRECTOR OF SALES AND ENGINEERING

Fawick Airflex Co., Inc.

The Airflex clutch was developed in an effort to apply sound and thoroughly proved mechanical principles to obtain the maximum efficiency of power transmission using conventional materials. Airflex clutches are manufactured in five basic design types.

CLUTCH TYPES

In three of the types, the torque is transmitted through the rubber tube, thus providing resilient cushioning action between the driving and the driven shafts. Type CB, shown by Fig. 14-99, with dimensions, is a constricting design with the friction-shoe assemblies mounted on, and driven by, the rubber tube. Type EB is an expanding design with the friction shoes similarly mounted. Type ER is an expanding design driving through direct contact between the rubber tube and the clutch drum. These types are shown by Fig. 14-100 with dimensions. In two of the types, the torque is transferred directly through torque bars from the friction-shoe assemblies to the clutch housing, the air tube acting only as the means of applying uniform pressure. Type C is a constricting design, and type E is an expanding design. These types are shown by Fig. 14-101 with dimensions. The variations in construction of the several types are shown in Figs. 14-99, 14-100, and 14-101.

Common Characteristics for all Types.

1. All portions of the friction block contact the drum at equal velocity.
2. All friction blocks contact the drum with uniform pressure.
3. Approximately 360-deg radial contact is obtained between friction blocks and the drum.
4. All designs are pneumatically operated.
5. Disengagement is complete when air pressure is released. When the clutch is in the released position, an open air space between the drum and the friction shoes eliminates any possibility of drag effect which would result in heat, wear, or noise.
6. Friction-shoe assemblies are removable and replaceable without special tools or equipment.
7. All types are self-compensating for wear and require no adjustment throughout the life of the friction block.
8. Automatic compensation eliminates any negative effects of misalignment since pressure balancing occurs in the air tube.
9. Control is accomplished by manually or electrically operated valve. This valve can be either of the "on-and-off" type or of the modulating (controllable variable pressure) type. Remote control or multiple-station control can be obtained through the use of solenoid-operated valves with proper accessory equipment.
10. Maximum heat dissipation is ensured since drum design permits maximum circulation of air.
11. The three types in which the torque is transmitted through the rubber tube ensure prolonged life and reduced maintenance on all power-transmission elements through the elimination of peak shock loads.
12. The three types in which the torque is transmitted through the rubber tube compensate automatically for accidental and reasonable angular- and parallel-shaft misalignment.
13. Since no adjustment is required, all possibility of improper adjustment is eliminated.

* Apply factors shown to starting torque load.

14. Smooth starting is obtainable through controlled application of the operating air pressure.

15. Applied torque can be sensitively regulated through a modulating (controllable variable pressure) type of control valve.

16. Torque limiting can be obtained through regulation of maximum pressure applied.

17. Location of control station can be determined independently of clutch location.

18. Minimum axial space is required for installation.

19. The standard clutch in the three types in which the torque is transmitted through the rubber tube combine the dual function of a flexible coupling and a clutch.

20. Type CB clutch is generally applicable to most industrial clutch requirements. It is equally suitable for those requirements where two shafts are to be connected and

for those applications where either the drum or the clutch element and supporting spider are bushed on a common shaft, with the other member keyed to the shaft. It makes available the greatest amount of peak-torque cushioning, as well as the reduction of vibration which would otherwise be mechanically transmitted. The rubber tube tends to eliminate these mechanical vibrations. In the type CB clutch, the rubber tube is permanently bonded to the steel rim at the time the rubber tube is cured. The friction-shoe assemblies are secured to the tube with removable shoe pins which are held in place by heavy lock wires. The friction-shoe assemblies consist of an asbestos-base synthetic-resin block permanently bonded (without rivets) to the cadmium-plated steel backing plate. These friction-shoe assemblies are removable and replaceable without use of special tools. The openings between adjacent friction-shoe assemblies are provided with stainless-steel cavity shields. These shields eliminate any possibility of harmful or destructive effect of any material that may accumulate between the friction blocks.

Service factors to be used in the selection of the proper size of an Airflex clutch are given in Table 14-101A.

Since the friction-shoe assemblies and the nonrigidly supported part of the clutch tube are subject to centrifugal-force effect, consideration must be given to the operating speed. Centrifugal-force effect at speeds up to 100 rpm is negligible. On applications operating at higher speed, proper correction for the operating speed should be made. The value of the necessary correction is shown on the service-rating chart. All torque ratings shown in the dimension tables for the various sizes of cluthces are based on 75 psi inflation pressure in the clutch tube. All Airflex clutches are suitable for operations at applied pressures up to 110 psi maximum. The necessary formulas to obtain the rating at pressures other than 75 psi are shown below the service rating graph (see Fig. 14-102).

The type EB clutch is generally applicable to most industrial clutch requirements where the operating speed is low. This limitation is imposed by the fact that centrifugal force on the expanding-type element may prevent positive disengagement on release of air pressure. It is equally applicable to those requirements where two shafts are to be connected and to those applications where either the drum or the clutch element and supporting spider are bushed on a common shaft, with the other member keyed to the shaft. Since the entire torque is transmitted through the rubber side wall of the tube, maximum cushioning against peak torques is obtained, and maximum elimination of mechanical vibration is effected. When installed as a flexible-coupling connection, compensation is provided for reasonable angular- and parallel-shaft misalignment. Torque ratings shown in the type EB dimension table are based on 75 psi inflation pressure in the tube. Correction of rating for higher or lower air pressures should be made through use of the formula shown below the type CB service-rating graph. The friction-shoe assemblies on the type EB are similar to the type used on, and described under, the type CB.

The type ER clutch is a special-purpose design intended for use on disconnecting clutch coupling applications, such as dual drives and stand-by drives. On such installations, the rubber-element assembly is properly mounted on the shaft, which normally remains idle. Inflation pressure in this type can be provided through a drilled hole in the shaft, a rotorseal and "on-and-off" valve from a compressed-air line, or be provided by manual inflation. On those applications where manual inflation is required, the element assembly is furnished with a tank valve similar to that used on automobile tires. The type ER is also suitable where low inertia values are involved and where an almost instantaneous braking function is needed. Typical of this type of installation are the brakes on the collapsible drums of tire-building machines. The drum is automatically collapsed by arresting the rotation of the shaft, allowing the inertia of the tire to unlatch the collapsing mechanism. On both the type EB and type ER, the rubber tube is permanently bonded to the steel rim at the time the rubber tube is cured. The torque ratings shown in the type ER dimension table (Fig. 14-100) are also based on 75 psi inflation pressure in the element tube.

The type E Airflex element may also be used on general industrial clutch or brake requirements. It is particularly suited to those requirements where frequent accelera-

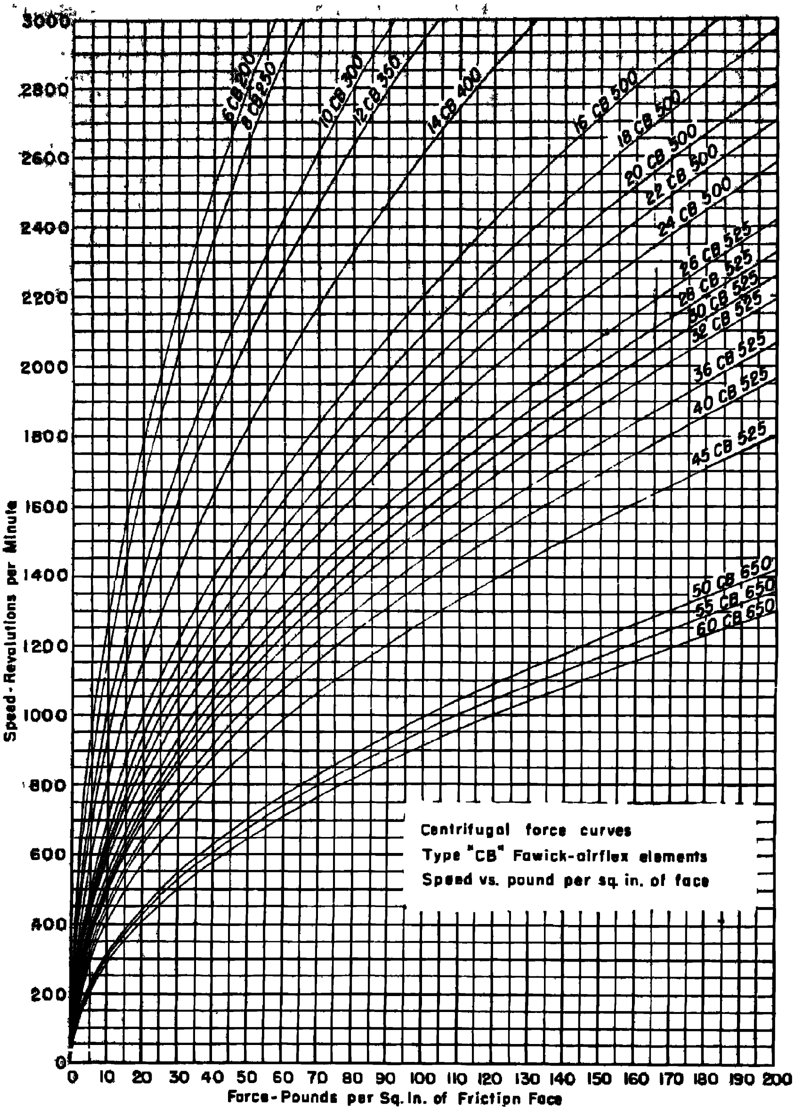

FIG. 14-102. Clutch service ratings.

For applications up to 100 rpm

$$\text{Required torque rating} = \frac{\text{hp} \times 63{,}000}{\text{rpm}} \times \text{service factor} \times \frac{75}{\text{minimum air pressure}^*}$$

For applications above 100 rpm

$$\text{Required torque rating} = \frac{\text{hp} \times 63{,}000}{\text{rpm}} \times \text{service factor}$$

$$\times \frac{75}{\text{minimum air pressure} - \text{centrifugal force}^*}$$

tion or braking duty is imposed or where continuous controlled torque slip is required. Typical of common applications are swing clutches on power shovels and drag lines; feed and return travel on sawmill carriages and similar reverse-travel mechanisms; slip clutches on coilers, slitters, and winders. Another typical application is drag brakes or differential drag mechanisms on ferrous and nonferrous metal, paper winders, coilers, and rewinders.

The type E element has also been employed on stationary Prony-brake-type applications. It is ideally suited to high-inertia starting-duty requirements and makes practical the use of a synchronous motor or normal-starting-torque induction motor of proper rating for the actual operating load, instead of the more expensive motor and control required by the high-inertia starting requirements if directly coupled to the drive.

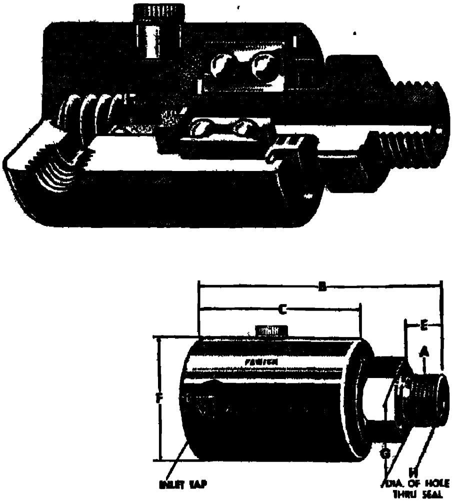

Fig. 14-103. ABC Rotorseal.

The Rotorseal

Size	Max speed, rpm	Max air pressure, psi	*A* th'd diam,	Dimensions, in.							
				B	*C*	*D*	*E*	*F*	*G*	*H*	Pipe tap
A	2,500	150	⅝-18 N.F.	3⅛	2	⅜	½	1½	⅞	¼	¼
B	2,000	150	⅝-18 N.F.	3 7/16	2¼	7/16	½	1⅝	⅞	⅜	¼
C	1,500	150	1-14 N.F.	4⅜	3	1 1/16	¾	2½	1⅜	⅝	½

This type is also ideally suited to cyclic braking requirements on equipment such as punch presses, shears, tile trimmers, and similar machines. On applications of this type, the motor can be started and allowed to come to full speed without load. The full running torque of the motor can then be utilized through controlled application of air pressure through a modulating valve to accelerate the driven equipment. Starting cycles as long as 3 min can be obtained. Where synchronous motors are preferred to obtain the benefits of power-factor correction, the use of this type of clutch permits continuous operation of the motor and cyclic or periodic use of the driven equipment.

Torque Ratings. The torque ratings shown under type E clutches are based on 75 psi inflation pressure in the tube. Correction for higher or lower operating pressures should be made through use of the formula shown under the type CB service rating graph. On continuous slip applications, the torque rating of the type E element is 40 per cent of the value shown in the torque rating column. This decreased rating is predicted on the use of a maximum of approximately 30 psi inflation pressure.

The type E clutch can be supplied with special high-heat-dissipating drums or with drums suitable for use with auxiliary water cooling. The type E clutch consists of two similar stamped-steel housings, one of which is provided with an opening to permit connection of the valve in the tube to the air supply. These housings are cadmium plated to prevent any damage from corrosion. The tube is an individual member supported by the steel housings. The friction-shoe assemblies consist of an asbestos-synthetic-resin-type friction block substantially secured to a cadmium-plated steel backing plate. This backing plate is mounted in an offset position on the friction block. This offset construction permits removal and installation of the friction-shoe assemblies without disturbing the housing mounting on those installations where provision has been made to permit drawing back the drum a sufficient distance to clear the friction shoes. The torque is transmitted from friction-shoe assemblies

through torque bars of substantial proportions to the steel housings. The friction-shoe assemblies are held in place in the housings and are retracted when air is exhausted by release springs inserted in a slot in the friction block and supported by lips on the housings. These release springs are of highest quality alloy spring-steel material and are cadmium plated to prevent corrosion. A series of release springs is available for each size of element. The choice of the correct release spring is based upon the maximum operating speed of the clutch (or brake) so that the necessary force to overcome the effect of centrifugal force will be available to ensure complete disengagement.

The type C element assembly is also applicable to either clutch or brake function. Its useful field of application consists of those requirements where heavy-duty acceleration or braking loads are imposed and where space considerations lead to a preference for a constricting type of unit. It is essentially applied on applications where the element may operate when disengaged at overrunning speeds higher than the speed at which the clutch normally operates. Typical of this type of application are cable-drum clutches where the free falling speed of the load on the cable may cause the drum to operate at speeds considerably higher than the speed obtained when the drum is driven by the prime mover. The construction of the type C element is similar to that of the type E, except that it is of the constricting type. The housing is a combination of cast Meehanite and steel-plate construction rather than steel stampings.

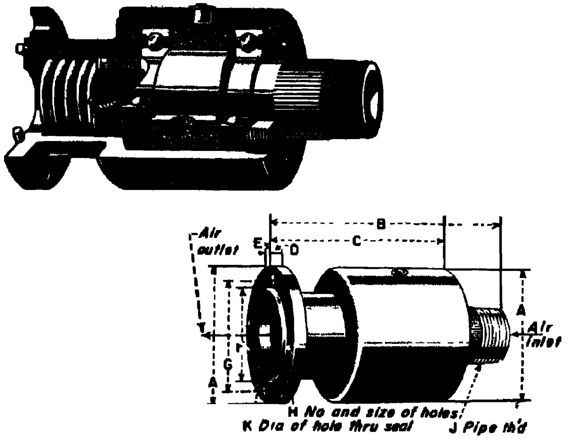

FIG. 14-105. RH Rotorseal.

The torque ratings for type C elements are based on 75 psi inflation pressure in the tube. Correction for higher or lower operating pressures should be made through use of the formula shown under the type CB service-rating graph.

THE ROTORSEAL

The Rotorseal (Fig. 14-103) is a positive seal for introducing air, liquids, or gases, under pressure, into a rotating shaft. It can also be used for vacuum applications.

The Rotorseal operates continuously or intermittently at high speeds in either direction.

As shown in Fig. 14-103, sealing is effected by a nonmetallic bushing held by spring pressure against a spindle face. Sealing surfaces are given the finest precision lapping obtainable. The spindle rotates on a sealed double-row bearing.

3/4	11673	5470	3 1/16	2 5/8	1 1/8	1 9/16	1 7/16	3/4	3/4	1 1/4	4 3/4	3/16
1	11674	5471	3 1/2	3 1/16	1 5/16	1 15/16	2	1	1	1 1/2	5 1/2	1/4

The Rotorseal is connected to the shaft simply by screwing the male end of the seal into a properly aligned, drilled, and tapped mating hole in the shaft end. The connection from Rotorseal to stationary piping should be made through a flexible hose connection. This prevents artificial loading of the Rotorseal bearings. Either rubber or flexible metallic hose connections can be supplied.

Two rotating elements on one shaft can be separately supplied and controlled from one shaft end with the dual-passage Rotorseal BD (Fig. 14-104). Where both shaft ends are available, four separate clutches can be individually actuated with two dual-passage rotorseals. Each line of the seal can be used to conduct a different medium (liquids, gases, etc.).

This seal is flange-mounted on any size of shaft by means of adapters designed for every type of application. Mounting components are recommended and available to suit the particular requirements of the job.

Flexible hose connections should be used between stationary piping and the dual-passage Rotorseal. This prevents artificial loading of the bearings. Either rubber or flexible metallic hose connections can be supplied.

Type RH Rotorseal (Fig. 14-105) is a single-passage seal for applications where large volumes of air, gases, or liquids are required. The operating principle of the type RH is identical with that of the smaller Rotorseal units.

It is flange mounted to a shaft end. The housing rotates, and the inlet is connected to stationary piping through a flexible hose connector.

The weight of type RH Rotorseals is very small, eliminating the need for auxiliary support arrangements. Decided space economy is also accomplished.

For use with other mediums than air, the manufacturer should be consulted for installation recommendations.

The quick-release valve (Fig. 14-106) provides a positive and efficient method of quickly discharging air under pressure from clutch or brake units, air cylinders, or any system where it is necessary quickly to evacuate air under pressure. Its operation is quick and positive, regardless of its location relative to the operating or control valve.

The valve operates on the principle of pressure differential. Normal discharge occurs through the control-valve discharge port until a 5-lb differential is developed in the quick-release valve. This actuates the discharge plunger, opening the exhaust port and exhausting air directly to atmosphere.

The unit is self-adjusting and requires no lubrication.

The standard quick-release valve is supplied with a male pipe-thread outlet connection, and a tube connection fitting on the inlet side. It is also available with an adapter for pipe-to-tube connection on the inlet side.

TORQUE CONTROL, TENSION CONTROL, AND TORQUE AMPLIFICATION

BY JAMES P. MADDEN, M.E.

Formerly Research Engineer, Bethlehem Steel Company

Torque control has always been a major problem in industrial-plant operations. Much has been done in the design of electric motors to solve this, but accomplishments have been in the direction of providing sufficient torque in the form of "minimum guaranteed" torque rather than accurate maximum torque.

It is of paramount importance that mechanical power drives have sufficient torque capacity available at all times to start equipment and keep it running under all reasonable load conditions, but excessive torque is frequently *undesirable and sometimes* the cause of serious breakdowns.

Torque control and tension control are synonymous in so far as the problem of the plant engineer is concerned because torque is the product of the pull (or force) multiplied by the radius at which the pull is exerted, whereas tension is the conventional term used to designate the pull exerted on a piece of material, usually in linear motion, without reference to the radius of the core or coil on which the material is being wound or from which it is being unwound. To produce any desired tension, it is necessary to maintain a torque or torques equal to the desired tension multiplied by the radius or radii at which the material is being wound or unwound.

The difference, therefore, between torque control and tension control lies in the type of apparatus used to accomplish the control.

TORQUE CONTROL

In designing or selecting a mechanical power drive with torque control for any piece of mechanical equipment, it is necessary to have the following information:

1. The torque necessary to start the equipment under the most adverse starting conditions. This is called "the starting torque."
2. The torque necessary to keep the piece of equipment running during all reasonable operating load conditions. This is called the "running torque."
3. The maximum operating torque which it is desired to impose on the equipment or motor. This is called "maximum overload torque" and is largely a matter of judgment by the plant engineer.

Inasmuch as the majority of engineers refer to starting torque, running torque, and overload torque in terms of horsepower, this practice will be followed as far as possible in this subsection.

In many instances the "running torque" will be the determining guiding factor in selecting the motor and the chain, belt, gears, or gear reducer which make up the drive. These are conventional drives and present no problem in torque control.

In some mechanical power drives, owing to the weight or mass of the driven equipment or the product which is being handled in the equipment, it takes considerably more horsepower to start than it does to run it. To meet this condition, a larger motor may be used or a motor with high-starting-torque characteristics. The first choice is objectionable because of increased motor cost and lower efficiency and power factor. The second choice is objectionable because high-torque motors develop a starting torque of from 240 to 300 per cent. This high torque is exerted instantly upon closing of the motor circuit, with the result that such torque is imposed on the component parts of the drive and the driven equipment under practically shock conditions. With machinery that is subject to frequent starting and stopping, the application of this high torque often results in damage to the drive, the machine, or the product being handled.

This condition is very similar to that which would prevail if a long heavy freight train were provided with an enormous locomotive which was capable of starting the train instantly and accelerating up to full speed in a few seconds. The couplers would undoubtedly be jerked out of the leading cars every time the locomotive started.

Starting shock can be materially alleviated by the use of wound-rotor motors with suitable controls which provide slow start and gradual acceleration. This method, however, is expensive and tends to complicate the drive.

The second item, "running torque" (or horsepower), is that which should determine the size of motor for maximum efficiency of operation.

The third item, "maximum overload torque" (or maximum horsepower), is of interest as a safety factor. The parts of all machinery and motors are designed for some definite fiber stress, and it inevitably follows that, if the maximum stresses for which the machinery is designed are exceeded, breakage will result, especially if the maximum load occurs suddenly, thus creating a shock condition.

An ideal arrangement would be where a motor would build up gradually to the horsepower capacity necessary to start a machine, and having done so, would accelerate the machine to full speed at a rate that would not impose more than the safe fiber stress on any of the parts, as determined by the designing engineer. This is what some engineers have called a steam-engine start. This ideal setup can be very closely approximated by the use of a piece of mechanical power equipment known as a slip-ring starter.

This device, which is of mechanical construction, is a modified form of centrifugal friction clutch whose torque capacity varies directly as the square of the speed of operation, and whose horsepower capacity varies as the cube of the operating speed. For any given horsepower capacity, therefore, the higher the speed, the smaller will be the size of this device.

Practically every clutching device has a slipping or releasing point which is variable because it is directly dependent on the coefficient of friction of the friction material used. As the coefficient of friction of all friction linings varies widely at any and all times, friction devices as such are not sufficiently accurate or constant to be used as safety devices. The slip-ring starter, however, possesses a novel characteristic in that, although the coefficient of friction will vary as much as 50 per cent, its torque and horsepower capacities do not change substantially. This seemingly paradoxical situation is explained in the following mathematical treatment of the subject.

Theory of the Slip-ring Starter. There are three elements in the slip-ring starter: the spider, the friction band, and the drum. (In actual construction there are two friction bands, but this is merely to provide a balanced drive; theoretically, one band is sufficient.) The spider is keyed on the motor shaft and the drum on the shaft of the driven machine; the band is weighted and lies inside the drum, one end engaged by a lug projecting from the spider, by which the band is pulled around. The rear or trailing end of the band is free. As the motor speeds up, centrifugal force causes the band to expand and exert a frictional drag on the drum, the torque thus transmitted depending upon the motor speed, diameter of the drum, and weight of the friction band.

Torque transmitted by the slip-ring starter is practically independent of coefficient of friction. Such a characteristic completely differentiates this from ordinary friction devices and results in a constancy which is novel and apparently at variance with previous engineering experience. Since the operation of the slip-ring starter depends upon a combination of wrapping friction and centrifugal force, both of which involve principles difficult to visualize, explanation of the constancy of transmitted torque cannot, unfortunately, be given in simple words but must be expressed in the form of a mathematical proof.

Figure 14-107 shows a drum which may be considered stationary and within which an arm revolves, in the direction indicated by the arrow. At its extremity this arm is connected to one end of the flexible weighted friction band. Now, let the centrifugal force per unit length of the friction band = c. (This will depend upon speed, weight of band, radius of drum r, etc., all of which are considered constant.) Taking the elementary portion of band da, the radial force due to centrifugal effect will be $cr\,da$, part of which, however, is neutralized by the tension in the band. In Fig. 14-108, let these tension forces be f and $f + df$. Then the radial resultant will be $f \sin (da/a) + (f - df) \sin (da/a)$, or simply $f\,da$.

The residual of radial force P pressing the band against the drum will then be $cr\,da - f\,da = P = (cr - F)\,da$.

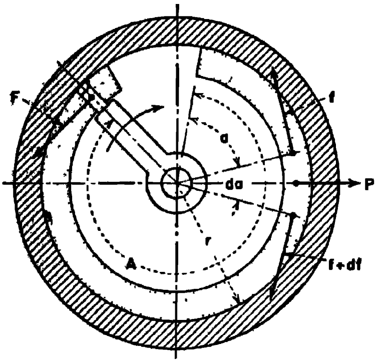

FIG. 14-107.

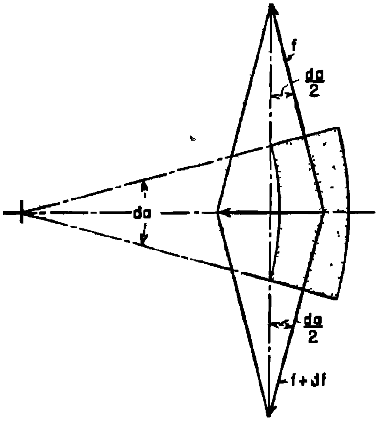

FIG. 14-108.

The tangential force due to friction will be $P\mu$, where μ = coefficient of friction. But $P\mu = df$; then $df = (cr - f)\mu\,da$.

Integrating this and noting that when $a = 0, f = 0$, we get

$$\log [cr/(cr - f)] = \mu a \qquad \text{or} \qquad f = cr\,[1 - (1/e^{\mu a})]$$

(e is the logarithmic base 2.71828).

The torque T on the arm will be rF.

$$T = rF = cr^2\,[1 - (1/e^{\mu A})]$$

where F and A are the values of f and a corresponding to the point of attachment of the arm.

This formula shows that a wide change in μ causes only a slight change in the torque transmitted

To take extreme values of μ, assuming $A = 6$ radians, where

$$\mu = 0.35 \qquad T = 0.875cr^2$$
$$\mu = \text{infinity} \qquad T = 1.000cr^2$$

Thus it is obvious that the coefficient of friction, while necessarily a factor in the formula, here appears in such a manner as to render it of very little importance in the final answer.

Figure 14-109 shows a curve of the horsepower transmitted by a slip-ring starter operating on the foregoing principle at different values of the coefficient of friction. The full line portion of the curve, from coefficient 0.35 up, covers the working range of the device. While this range may seem extreme, as a matter of fact any friction material may be expected to vary as much as this under normal operating conditions for short periods, owing to effects of heating, wear, dampness, glaze, etc.

The purpose of the slip-ring starter now becomes apparent. The coefficient of friction cannot be stabilized or controlled, but as shown mathematically and illustrated by the starter curve, these variations have practically no effect on the final result.

The example shown is that of a unit designed to transmit power of 1.15 hp. At 0.35 coefficient it transmits 1.1 hp. As the coefficient of its friction bands rises, the power transmitted is shown in the curve as approaching but never reaching the line of 1.25 hp.

The curve Fig. 14-109 explains the action of the starter in providing against injurious overload.

Application Characteristics. The following application characteristics are obtainable with a slip-ring starter:

1. Load-speed acceleration can be varied from a few seconds to several minutes.
2. Motor, driven machine, and transmission equipment are relieved from injurious shock and strain.
3. Simplest electrical starting equipment can be used.
4. The motor starts under no load and is free of load until it reaches almost full speed.

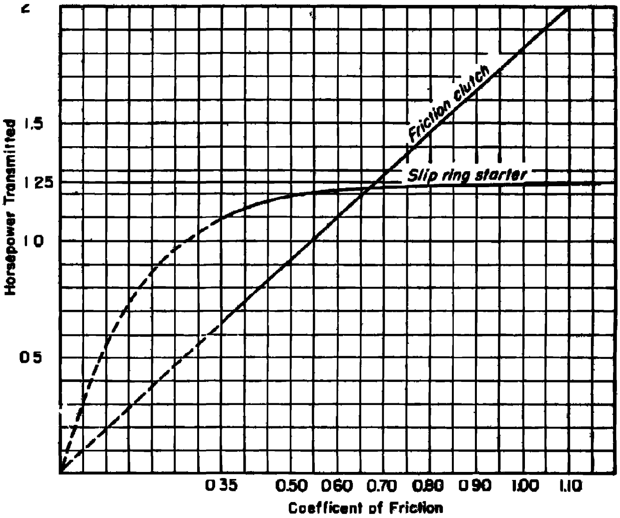

FIG. 14-109. Chart showing relation of horsepower to coefficient of friction.

5. The device is inherently an overload device. It slips as soon as the load reaches its capacity but continues to exert its torque and resumes positive drive as soon as the load returns to the predetermined limit.
6. The capacity to transmit torque is the same whether the driven machine is operating at full speed or is in a stalled condition.
7. Any desired overload factor can be obtained.
8. The entire unit consists of a small number of separable parts which can be disassembled and reassembled by any mechanic.
9. When acting as a coupling between the motor and the driven machine, the starter, in addition to its other characteristics, serves as a flexible coupling.
10. It is applicable to any constant-speed prime mover and in certain cases to variable-speed prime movers for horsepower capacity ranging from fractional to 1,500 hp.
11. The friction lining is the only wearing part. It usually lasts for from 4 to 10 years and can be cheaply and quickly renewed.
12. Slippage occurs only in starting and in cases of overload.
13. Accuracy of performance is maintained throughout the life of the unit.
14. The device can be incorporated as an integral unit with flat-belt pulley, chain sprocket, V-belt sheave, or gear pinion.

Figure 14-110 is a chart which shows a typical situation in which a motor is equipped with a slip-ring starter with a capacity of 125 per cent of the motor rating. The motor starts under no load, and as it accelerates to full speed, the torque and horsepower capacity of the slip-ring starter develop very gradually at first, which serves to take up the slack in chains, belts, or gears of the drive before applying the full torque.

The "driven machine" starts to turn over as soon as the slip-ring starter has sufficient torque capacity to overcome the frictional or other load. However, the driven machine starts slowly, and most of its acceleration takes place after the motor has reached full speed. The motor is under the load capacity of the slip-ring starter until the driven machine reaches full speed, and then it drops off to the running load.

In Fig. 14-111 are shown several motor-speed torque curves of commonly used electric motors. The curves numbered 5 to 13 are the torque capacity of different slip-ring starters which range in capacity from 103 to 270 per cent of the full-load torque of the motor.

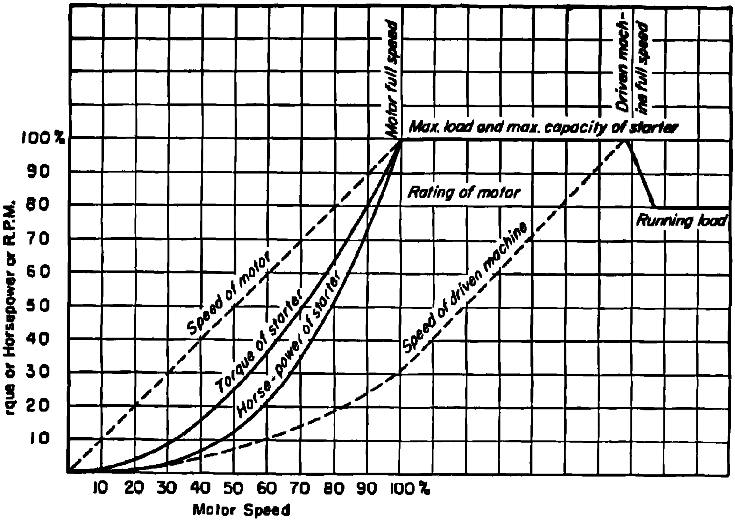

FIG. 14-110. Chart showing smooth gradual start and acceleration of driven machine and no-load start of motor.

The nature of the starting conditions or predetermined overload release of the machine to be driven will determine the selection of the correct size of slip-ring starter for the job.

From Fig. 14-111 it will be seen readily that the general-purpose or normal-starting-torque motor is best adapted for starting against a very high starting-torque load caused either by inertia or breakaway conditions. The general-purpose motor, because of its extremely high pull-out torque, provides the highest possible torque for starting when it is equipped with a slip-ring starter.

It will also be seen that the high-amperage starting current lasts only while the motor itself is getting up to speed. When the maximum load of the slip-ring-starter capacity comes on, the current has dropped to very reasonable proportions. In practically every case, therefore, the motor can be started on full voltage.

Having established the fact that accurate torque control can be obtained, it is now possible to approach the problem of providing an economical and efficient motor drive with the following salient facts in mind:

Any normal-starting-torque or general-purpose squirrel-cage motor which will run the driven machine will also start it. The horsepower rating of the motor will be determined by the running load on the driven machine. The motor can be started on full voltage provided there are no local conditions that make this prohibitive. In this connection it should be mentioned that, whereas in extreme cases it may not be permissible to start under full voltage with a solid coupling on the motor because of the long-drawn-out starting current, it is frequently permissible to do so on account of the very short period of inrush current which prevails when the motor is started under no load.

As a guide in determining the correct capacity of slip-ring starter which should be used for driving various machines and equipment, Table 14-102 shows the relation between the motor rating and that of the slip-ring starter. These figures are based on actual industrial operating experience.

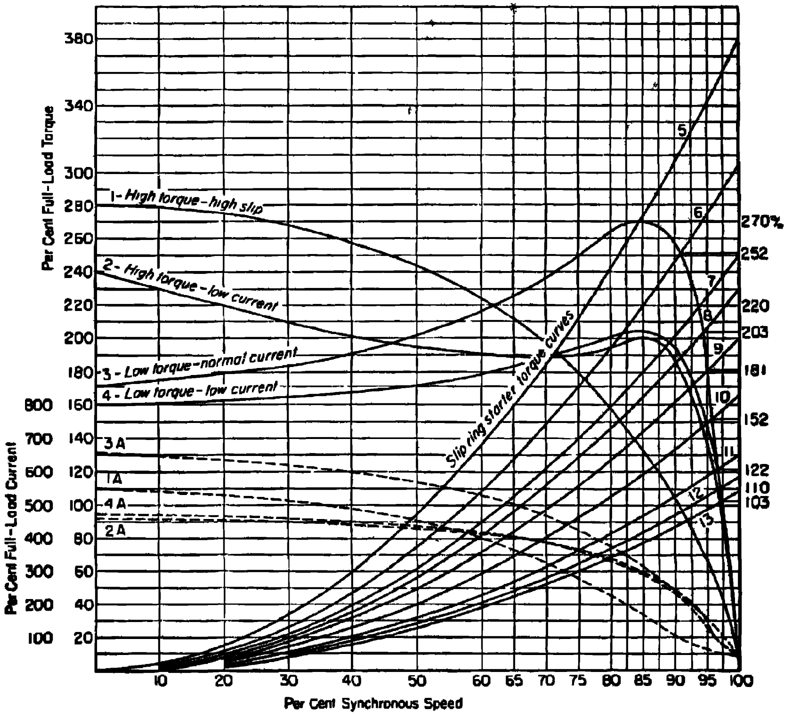

Fig. 14-111. Chart showing several capacities of slip-ring starters which can be applied to motors, to suit various load conditions.

After the capacity of the slip-ring starter is decided upon, either a V-belt, flat-belt, chain, gear, or direct-connected drive may be used. The size of the slip-ring starter can be selected from Table 14-103, and the dimensions can be obtained from Table 14-104.

A large number of sizes of slip-ring starter other than those listed are available, but those given in Tables 14-103 and 14-104 will be sufficient to guide the plant engineer in making his preliminary arrangements.

The majority of mechanical power drives run continuously in one direction, but where operation in both directions of rotation is required, slip-ring starters correspondingly are made reversible, and the same accuracy of torque control prevails in both directions of rotation. This is provided for in the construction of the driving bands.

Table 14-102. Relation of Motor and Slip-ring Starter Rating

Driven machine	Ratio of slip-ring-starter rating to motor rating, per cent	Reasons for using slip-ring starter
Dough mixers, chance coal cleaners, vacuum pans, pumps handling high-viscosity materials, machines subject to short-period high-peak loads.	250:270	Extremely hard-starting breakaway load. Low-starting-torque motor can be used which reaches full speed to exert its maximum "pull-out" torque before it encounters any material load.
Chaser mills, coal shakers, hammer mills, pulverizers, multiple-plunger pumps, jute spinners, heavy textile equipment, cardboard machines, chance cones, cards, etc.	200:225	Hard-starting heavy equipment with occasional high-peak loads.
Conveyors, fans, centrifuges, air compressors, lead pumps, refrigerator compressors, pickers, bridge-cable wire wrappers, rovers, shears, punches, Bradford breakers, barking drums, shakers, air pumps, blowers, ball mills, chemical equipment, turbine drives, coal breakers.	150:200	General run of industrial equipment, fairly hard start with maximum load limitation.
Silk winders, spinners, nylon equipment, cable-taping machines, light textile equipment, gasoline-engine drives, crockery and china conveyors, light machinery with very slow start.	100:150	Light slow-starting equipment with load limitation to low percentages of overload.

The coupling type of slip-ring starter, shown in Fig. 14-112, consists of a driving spider *A*, driven drum *B*, and driving bands *C*. The direction of rotation is indicated by the arrow.

The reversible-coupling type of slip-ring starter for operation in both directions of rotation is illustrated by Fig. 14-113. It will be noted that the driving bands are equipped with driving cleats at both ends and that the spider has two driving arms for each band.

The torque effort is transmitted from the driven spider to the bands through flexible rubber cushions. In the case of the coupling type, these rubber cushions, by their flexing, will compensate for angular misalignment and eccentricity. However, in erection, a definite effort should be made to obtain accurate alignment.

The pulley and sprocket type of slip-ring starter is shown in Fig. 14-114. This type is provided with a bearing of renewable bronze bushings in which the driving spider rotates during slipping periods. A flat-belt pulley, V-belt sheave, sprocket, or gear can be mounted on the hub of the drum (see Figs. 14-115, 14-116, 14-117). A coupling-type starter is shown by Fig. 14-118.

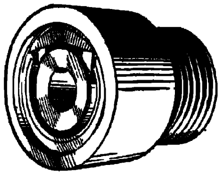

Fig. 14-115. Slip-ring starter arranged for V-belt drive.

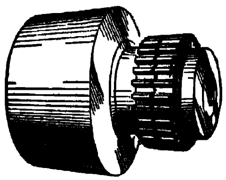

Fig. 14-116. Slip-ring starter arranged for silent chain or gear drive.

The pulley, sprocket, or gear is located in the same position in relation to the motor shaft as it would be if it was mounted directly on the motor shaft. If the diameter of the pulley or sprocket is small, instead of making them as separate pieces, they can be made as integral parts of the slip-ring starter by cutting the grooves or teeth on the hub of the drum.

The bearing functions for short periods and very infrequently. Therefore very little lubrication is needed. Radial holes in the motor shaft and driving spider convey the lubricant into the bearing reservoir from the lubricating fitting which is screwed into the end of the motor shaft.

Normally one end of the drum is left open, but when deleterious atmospheric conditions exist, a "cover" is used to protect the bands and drum surface. This is illustrated in Fig. 14-114.

Applications Where Torque Control Is Advantageous. It is not possible to give a complete list of equipment in the driving of which torque control is desirable or necessary. The majority of machinery presents no problem of this character, but there are a certain number of drives where high starting torque causes so much trouble that the attention of plant engineer is demanded continuously.

These drives include ball mills, grinders, pulverizers, hammer mills, dough mixers, compressors, heavy fans, cards, conveyors, centrifuges, drawbenches, rotary cutters, etc.

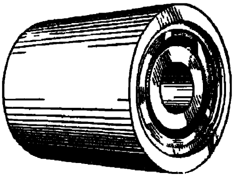

FIG. 14-117. Slip-ring starter arranged for flat-belt drive.

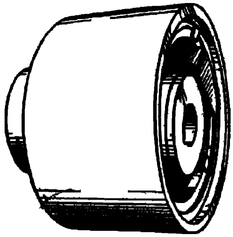

FIG. 14-118. Slip-ring starter, coupling type, for direct drive.

The high starting torque is caused by the inertia of the large masses which have to be set in motion. If the drive is of the positive type with no provision for slippage, motion of the driven machine begins instantly, and inasmuch as the motor acceleration is very rapid, the acceleration of the driven machine will be correspondingly so. This produces very high fiber stresses in every part of the drive causing either early fracture or fatigue which eventually results in breakdown.

Practically all the machines mentioned above can be started and driven satisfactorily and with high efficiency by general-purpose motors in combination with torque control. The maximum torque imposed may be as low as half of that which would normally be required. In addition, the elimination of the shock conditions is practically a positive guarantee against fractures or damage. The maximum operation load will determine the maximum horsepower capacity of the slip-ring starter.

Another high-starting-torque condition is found on machines in which the inertia factor is low, but where there is a breakaway load resistance which will exist for periods of time varying in length from a few seconds to several minutes. These machines are dough mixers, vacuum pans, pumps handling high-viscosity liquids, chance coal cleaners, and several types of chemical equipment. The high starting torque is caused by the fact that the machines contain materials in a state of rest which must be agitated or moved bodily by an agitator of one form or another. A slip-ring starter with a torque capacity equal to the pull-out torque of the motor, which will be from 250 to 270 per cent of full-load torque, will start these machines smoothly and safely. If torque control is not used, it will be necessary to use a wound-rotor motor with the necessary electrical control to produce low speed with high torque, under which condition it is necessary that the operator exercise care and good judgment, or he is likely to damage the motor and the machine.

For the benefit of the engineer who is considering the problem of providing accurate torque limitation, the question of its application to several machines will be

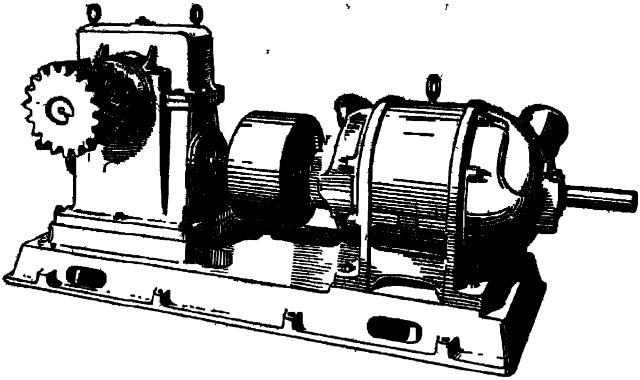

Fig. 14-119. Typical motor direct-connected drive.

discussed. Each machine is typical of a group requiring a specific percentage of overload horsepower capacity in relation to the full-load rating of the motor.

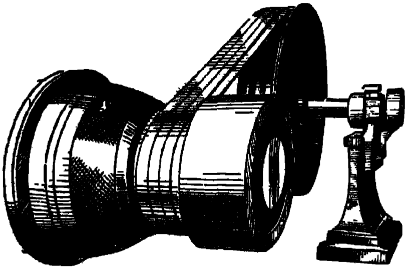

Fig. 14-120. Gill-box drive with pulley-type slip-ring starter.

1. A batch mixer, vacuum pan, cone coal cleaner, or agitator in which the impeller or agitator is immersed in a more or less solid material. To start any one of these machines requires a very high torque in order to move the impeller or agitator. It is assumed that the machine will be driven by a 50-hp 1,200-rpm motor. The correct size of slip-ring starter should have a maximum torque capacity of 270 per cent of motor full-load rating. Under this torque load a low-torque motor will operate at a speed of 1,020 rpm (approximately). The starter will therefore have a capacity of 119 hp at 1,020 rpm. The maximum running (pull-out) torque is used for starting, and it is applied gradually and without shock, and therefore there is no danger of shearing keys or twisting shafts. The starter will at no time allow the load on the motor or machine to exceed 119 hp.

2. Hammer mill, subject to plugging or occasional overfeeding. The mill is driven by a 150-hp 720-rpm motor. The normal running load is 145 to 155 hp. As a matter of judgment, it is desired that the maximum load should not exceed 210 per

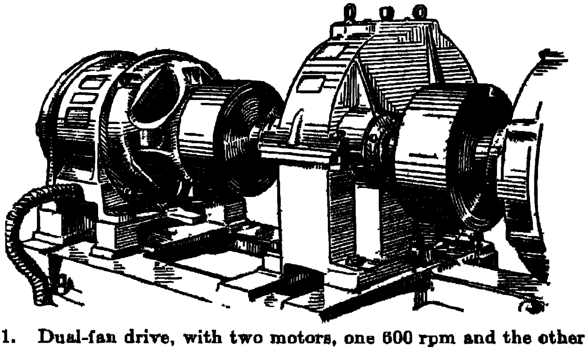

Fig. 14-121. Dual-fan drive, with two motors, one 600 rpm and the other 900 rpm.

cent of full-load rating. A 150-hp, low-torque motor will operate at 600 rpm under this amount of overload. The slip-ring starter therefore will have a maximum capacity of 300 hp. If the load goes beyond 300 hp, the starter will slip instantly.

3. Ball mill, conveyor, elevator, or air compressor. It is customary to regard these machines as requiring 200 per cent torque to start them with conventional drives.

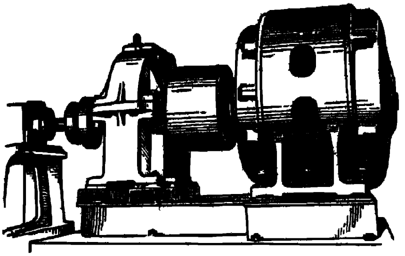

Fig. 14-122. Synchronous motor fan drive through reducer.

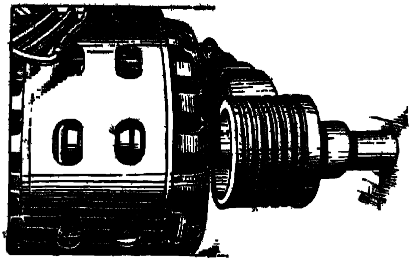

Fig. 14-123. Large pulverizer motor drive.

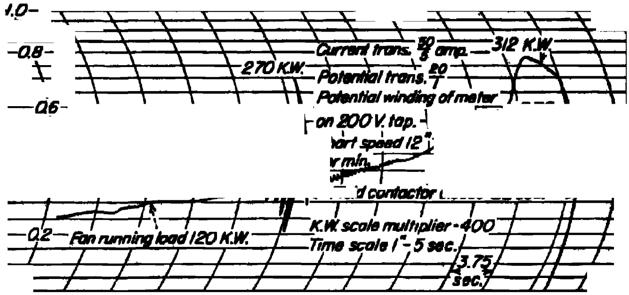
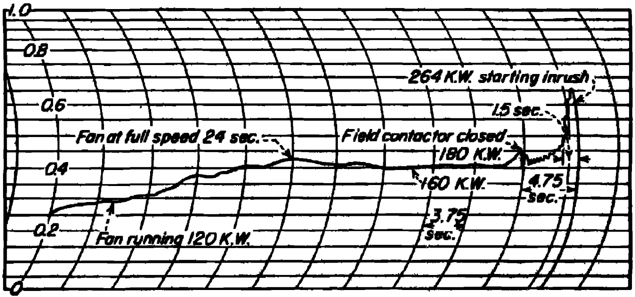


Curve with motor coupled to fan through flexible coupling



Curve with motor coupled to fan through slip ring starter

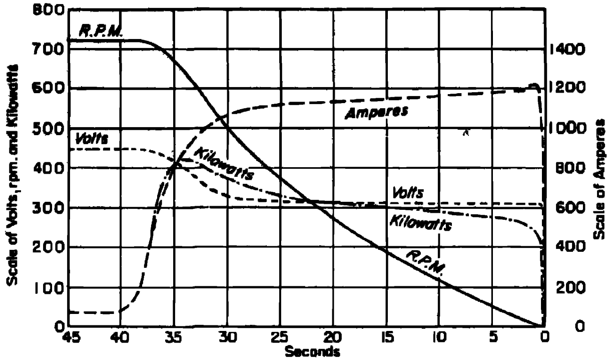
Fig. 14-124. Charts showing comparison between fan drive with flexible coupling and slip-ring starter.

This high torque is the result of inertia in the moving parts or the materials that have to be quickly set in motion. Assume a 50-hp 900-rpm low-torque motor is used for the drive, the correct size of slip-ring starter will be 75 hp maximum capacity at 840 rpm.

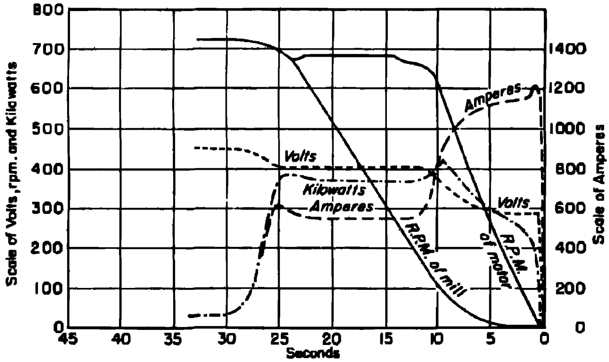
4. Large fan driven by a 200-hp 600-rpm motor. In this case the starting torque is caused entirely by inertia, and the time lapse to reach full speed is usually in the neighborhood of 30 sec. A slip-ring starter of 270 hp at 565 rpm will provide ample

torque to accelerate the fan against the air load which develops as the fan increases in speed and approaches full speed.

5. A conveyor that transports articles in process of manufacture must be started very slowly to prevent a jerky start which would disturb or upset the articles. The running load should be known with a fair amount of accuracy. If the conveyor itself is not too light in weight, a slip-ring starter with about 20 per cent capacity more than the running load will give a satisfactorily slow start. If a very slow start is desired, additional weight can be built into the driven side of the slip-ring starter to create a predetermined amount of inertia which will slow the acceleration down to any desired number of seconds or even minutes.



Motor coupled to pulverizer through flexible coupling



Motor coupled to pulverizer through slip ring starter

Fig. 14-125. Charts showing comparison between pulverizer drive with flexible coupling and slip-ring starter.

An example of this type of drive is in textile winding machines which are very light in weight. The product is also very light. These machines would normally start and reach full speed in about 2 or 3 sec, but the introduction of an additional amount of inertia will slow the acceleration down to 35 to 50 sec. This is very necessary in operations where light webbings or yarns are being transferred from one roll to another, and a quick start would be almost sure to break the material. In these light-power drives, the running load and not the motor rating should be used as the determining factor in arriving at the correct amount of torque limitation to be provided by the slip-ring starter.

An interesting characteristic of the slip-ring starter is that synchronous motors with low "starting torque" and low "pull-in torque" may be used in high-starting-torque drives in which synchronous motors would normally be inoperable. The slip-ring starter allows the synchronous motor to start easily and "pull in" to synchronous speed without any difficulty (see Figs. 14-122 and 14-123).

Figures 14-119, 14-120, 14-121, 14-122, and 14-123 show typical applications of slip-ring starters, and Figs. 14-124 and 14-125 are charts which show the starting conditions before and after installation of the slip-ring starter. The improvements which resulted are obvious.

LIMIT TORQUE COUPLING

The limit torque coupling is intended for use as an addition to the ordinary flexible coupling. It functions as a positive drive until the predetermined torque limit for which it is set is reached. At this torque load it slips but continues to exert the predetermined torque.

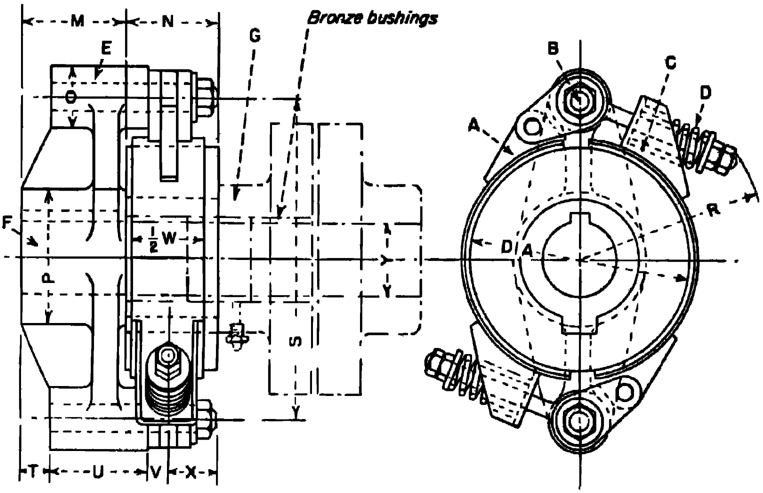


Fig. 14-126. Limit torque coupling.

In principle it is exactly the same as the slip-ring starter except that the pressure on the friction lining is provided by helical steel springs instead of centrifugal force.

It is particularly suitable for operation at low speeds, below 500 rpm. It has the same accuracy, as to torque and horsepower capacity, as the slip-ring starter. It slips in one direction only, but the bands can be reversed for either direction of rotation.

It is primarily intended for use on apparatus that is subject to extreme overload conditions or jams, and it is used definitely to limit the number of foot-pounds of torque, or fiber stress, which can be imposed on the weakest shaft or other part of the machine to a predetermined figure.

It can be tested periodically to check its accuracy and adjustment.

The limit torque coupling is symmetrical and therefore balanced, and it transmits a balanced torque at all times. It can be adjusted to slip at any desired load between 80 and 100 per cent of its maximum capacity.

Referring to Fig. 14-126, it will be seen that one end of each band *A* is anchored to a driving pin *B*, and the other end *C* is also attached to this same driving pin but through the medium of a helical spring *D*.

The spring pulls the band around the drum and applies the necessary pressure on the friction lining, thereby gripping the drum with the correct amount of pressure to prevent slipping until the predetermined torque load is reached.

In case of lining wear, the spring will become longer, but by adjusting it back to its correct length, constancy of torque capacity will be maintained.

Table 14-105 gives the dimensions of several sizes of limit torque couplings and their torque capacity in foot-pounds.

It should be observed that the driving arm *E* is keyed to shaft *F*, and one-half the standard coupling *G* is free on the shaft and preferably fitted with bronze bushings.

Table 14-105. Limit Torque Coupling Dimensions

TENSION CONTROL

Accurate tension control is obtained in an unwinding operation by providing a brake with a torque retardation which is proportionately lessened as the diameter of the coil of the material being unwound is reduced.

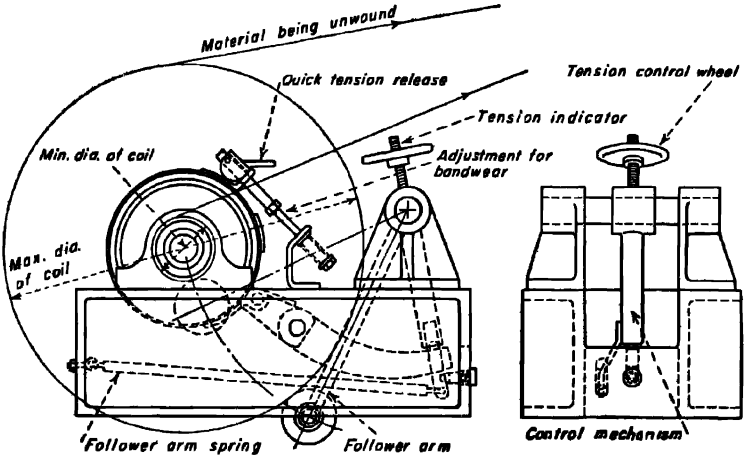

FIG. 14-127. Typical tension control for unwinding.

In the winding operation the conditions are reversed, and the torque exerted by the winder must be increased in direct proportion to the diameter of the coil of material being wound.

Obviously, therefore, there must be some connection between the coil of material and the brake or mechanism which determines the amount of the torque or tension.

In the tension control illustrated in Fig. 14-127, a follower arm or lever is so mounted that its end contacts the surface of the coil of material and follows it from the maximum coil diameter down to the minimum diameter. It is fitted with a roller of suitable diameter and length so that under a comparatively small pressure the material will not be marked or damaged.

The follower arm may also be connected by levers, shafts, and links which transmit its motion to the control mechanism.

The control mechanism contains a calibrated spring which exerts a pressure on the curved lever. The radius at which the spring imposes its pressure is directly controlled by the diameter of the coil of material. As the coil of material gets smaller, the radius at which the spring acts becomes less, and the torque capacity of the brake bands is less in proportion. The tension on the material remains constant throughout the operation.

The amount of tension on the material can be regulated within wide limits by adjusting the compression of the spring. The amount of tension is indicated by the amount of the projection of the indicator rod which projects above the "control handwheel." The amount of tension can be regulated up or down at any time, either at rest or during unwinding operations.

The tension will be constant, regardless of friction conditions and variations, at any amount of tension within the maximum and minimum ranges of the device with an accuracy of 1 per cent. The reason for this phenomenal accuracy in a purely frictional device is explained in the following discussion.

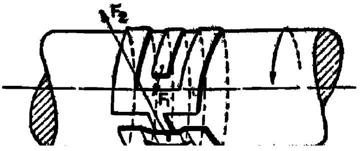

FIG. 14-128.

Theory of This Tension Device. Why the Pull Is Constant Regardless of Wide Variations of the Coefficient of Friction. The principle on which a reel tension works is as follows: In Fig. 14-128, F_1 and F_2 represent the forces on the two ends of the brake band illustrated. With the drum turning in the direction of the arrow, the relation between these two forces is represented by the usual formula for wrapping friction

$$(F_2/F_1) = e^{\mu\alpha}$$

where e is the logarithmic base (2.71828), μ is the coefficient of friction of the brake lining, and α is the angle of wrap in radians.

The retarding force T which is applied to the brake drum is expressed by the following equation:

$$T = (F_2 - F_1)$$

and therefore

$$T = F_2[1 - (1/e^{\mu\alpha})]$$

In the above equation, the value of α being determined by the design of the brake band is constant. In order to determine the effect of a change in the coefficient of friction, let us take a common value of this quantity, say $\alpha = 11$ radians, and assume for the moment that F_2 is 100 lb. Solving this equation for two extreme values of the coefficient of friction, where $\mu = 0.35$ and $\mu = 0.9$, in the first case T will equal 97.921 lb, and in the second case T will equal 99.995 lb.

Therefore, with this extreme variation of the coefficient of friction, the retarding force varies only 2 lb, which for practical purposes can be considered constant. With the ordinary friction brake, the braking force varies in direct proportion to the coefficient of friction, and if such a brake gave a retarding force of 97.921 lb with a coefficient of friction of 0.35, it would have a retarding force of about 252 lb with a coefficient of 0.9.

In the above discussion, the force (or torque) F is constant, whereas, of course, with a roll of material whose diameter is continually changing, the torque must be proportional to the roll diameter in order that the pull or tension may be constant. In the tension control herein described, this condition is provided for by the "follower lever" (or arm), which by its movement increases or decreases the torque proportionately.

TORQUE AMPLIFICATION

Many operations in industry are such that they must be performed manually because of widely varying conditions as to speed of movement or degree of movement. If the operation requires considerable effort, it is necessary to provide more or less gear reduction to make the mechanical advantage such that the operation can reasonably be performed by the human hand.

Sometimes this results in so much gear reduction that the operation becomes extremely slow, and if less gear reduction is used, the effort becomes too laborious.

Some of these manual operations are the operation of large valves, feeding heavy plates into punches, screw downs for strip mills, inching and maneuvering single-purpose machines, tilting heavy ladles, etc.

All these operations call for variability of movement from time to time which can only be determined by the judgment of the operator and at the time the operation takes place.

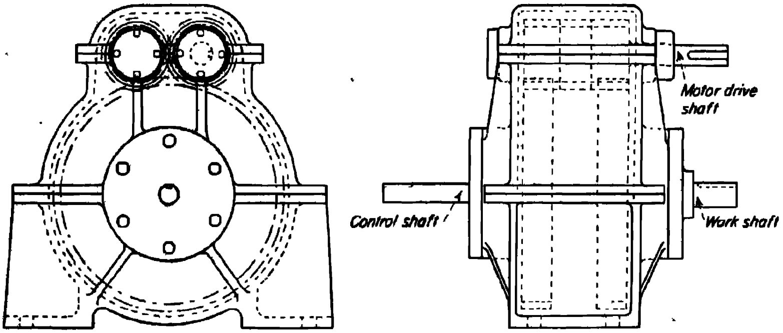

FIG. 14-129. Reversible torque amplifier.

It is generally recognized that a man cannot do more than about 1/10 hp of work turning a crank on a winch or pump. If, however, he has to be precise in his movements, such as in the adjustment of a heavy plate for punching holes with reasonable accuracy, which calls for frequent starting, stopping, and reversing movements, he will only be able to do a small percentage of 1/10 hp.

When a man is obliged to exert a large effort to turn over a machine for setting up or correction, it has been found that he cannot stop with the necessary precision accuracy.

The mechanical torque amplifier is a device that permits the operator to draw on the power of a continuously running motor by the exertion of only one-tenth of the torque effort needed to perform the operation. In effect, the torque amplifier gives the operator the use of ten times his own strength without any loss of that sensitivity of touch which he normally possesses. He can start and stop as he would on his own power, and he can make his movements as fast or as slow and as variable in speed as he would on his own power.

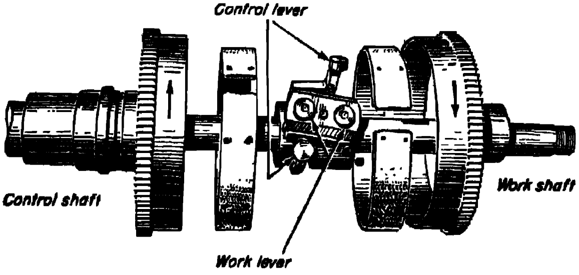

FIG. 14-130. Disassembled view of torque amplifier drums, bands, etc.

Referring to Figs. 14-129 and 14-130, which show a torque amplifier used for manual operation of the screw downs on a rolling mill, it will be noted that there are two drums which rotate continuously in opposite directions. The drums are driven by conventional spur gears and an electric motor connected to the "motor drive shaft."

Inside each drum there is an internal expanding friction band. On the "control shaft" there is a double-armed lever, the arms of which are staggered. Each arm of this lever engages in a hole in the trailing end of each band. On the "work shaft" there is also a similar double-armed lever whose arms engage in holes in the leading ends of the two bands. The "control shaft" and "work shaft" are physically connected to each other through the medium of the friction bands which repose with light touching contact within the drums.

Any movement of the "control shaft" will expand one of the bands pressing it against the drum and will contract the other band by a like amount. With the drums rotating in opposite directions, as soon as either band is expanded and makes pressure contact with the drum, the drum tends to drag the band along with it. As the band is quite flexible, the servo action increases the effort applied by the control shaft so that the front or leading end of the band presses against the arm of the lever of the "work shaft" with a greatly increased pressure. This increase in effort is represented by the equation:

$$(W/c) = e^{\mu\alpha}$$

where c = control effort
W = resultant work effort
e = natural logarithmic base (2.71828)
μ = coefficient of friction
α = angle of wrap of the band, radians

In Fig. 14-130, $\alpha = 5.9$, $\mu = 0.4$, and assume that $c = 5$ ft-lb. Then $W = 50$ ft-lb. The amplification is 10.1. The difference in the torque efforts between 50 ft-lb and 5 ft-lb is furnished by the electric motor through the "motor drive shaft."

It is obvious that an average man is not capable of exerting a torque effort of 50 ft-lb for any appreciable length of time. Moreover, his rate of motion would be very irregular, and he could not stop at any specific point with accuracy. Exerting an effort of only 5 ft-lb, he is capable of turning a crank of 1-ft radius easily and with a smooth regular motion at any rate of speed from 1 up to about 60 rpm, and he can stop at any desired point on the circle with an accuracy of plus or minus $\frac{1}{64}$ in.

The smallest fractional movement of the "control shaft" causes an exactly similar movement of the "work shaft."

The torque amplifier can be applied to operations requiring one-way or reciprocal movements in either a straight-line or circular motion.

With some applications the work force may be so large that an amplification of 10:1 is not sufficient to keep the "control force" down to a figure which is reasonable for a man to exert under the existing operating conditions as to frequency and continuity of effort. In such cases, it is possible to provide larger amplification by increasing the angle of wrap from 5.9 radians to 11.0 radians which will give an amplification of 80:1.

In Fig. 14-129, the "control shaft" was fitted with a 15-in. diameter handwheel, and the "work shaft" was connected through gearing to the screws of the rolling mill which determine the thickness of the material being rolled. Each revolution of the handwheel produces a change of 0.001 in. in the thickness of the material. It is therefore possible for the operator to adjust the rolls with extreme accuracy to produce any desired thickness of material. The effort required was approximately 5 lb on the handle of the 15-in. diameter handwheel.

A 1-hp gearmotor was used to furnish power to the revolving drums. Full power is used only while the "control shaft" is being turned. When the "control shaft" is at rest, the motor is subjected to merely an idling load.

An additional use for the torque amplifier is where synchronization of motion has to be provided between a very light piece of apparatus and a relatively massive piece of equipment. This can be done by installing a torque amplifier with a torque amplification of 100:1. The light apparatus is connected to the control shaft and the massive equipment to the work shaft of the torque amplifier. The massive equipment will then be driven by the light apparatus at exactly the same speed and will impose only one-hundredth of the torque load on the light apparatus.

BEARINGS FOR INDUSTRIAL ELECTRIC MOTORS*

BY J. W. SAMZELIUS

Mechanical Engineering Section of the Motor Division, Westinghouse Electric Corporation

INTRODUCTION

The electric motor is, from a mechanical viewpoint, the simplest of all power sources. This simplicity, as is usually the case with simple and functional designs, is the reason the electric motor is so dependable and easy to operate. By pressing a button or throwing a switch automatically, a motor may be started on a year-long continuous run or a short predetermined working cycle with no further attention and perhaps under very adverse conditions, such as heavy overloads, a gritty and dusty surrounding atmosphere, which may in addition be loaded with corrosive or explosive gas fumes, extremely hot or extremely cold surroundings, nearby water spray, or even submersion in water or other liquids.

These characteristics of the electric motor have become so well associated with the concepts of what the motor will stand that also the bearings, although no different from the bearings in any other machine, are expected to give equally good service with little or no attention. The design and the selection of proper bearings for the electric motor has therefore become a very important feature with all motor manufacturers. Much money and extensive engineering efforts have been expended by the leading manufacturers in attempts to make the bearing performance match, as nearly as possible, other features of the electric motor.

If a motor is ordered and built for a particular purpose to operate under certain known conditions, the bearings may be designed or selected to meet such purpose or condition, and the experienced designer may not have much difficulty in making the proper choice. In the majority of cases, however, the designer of the motor does not know the purpose for which the motor will be used or under what conditions it will operate, and therefore the problem is usually to select a bearing, which may be classed as universal, to take care of most prevailing conditions.

The purpose of this subsection is to clarify some of the reasons governing the selection of certain bearings for use in electric motors.

SLEEVE- AND ANTIFRICTION-TYPE BEARINGS (GENERAL)

Sleeve Bearings. A sleeve bearing is the stationary support or guide for a revolving shaft. Usually the bearing is made from a metal having very different characteristics and properties from the material in the shaft. As one of the desired characteristics is softness, low strength is a consequence. Therefore the bearing is usually made in two parts, a soft, thin lining for wear and adaptability and an outer shell for the support of the soft lining. In machines with very rigid shafts, where the deflection of the shaft inside the bearing is negligible but where shock loads and severe vibrations would pound out a soft lining, as, for example, in railroad trucks and in crankshaft bearings for large internal-combustion engines or in geared applications, the bearings are usually made from comparatively hard bronzes without lining or with a very thin lining, as thin as 0.005 in.

Some linings are made from expensive silver alloys, others from inexpensive lead-base babbitt. Recent experiments with an aluminum–tin alloy bonded by a process developed by the Al-Fin Corporation of Jamaica, New York, is claimed to be good. The Aluminum Company of America is offering solid wall bearings from its alloy No. 750, intended for large diesel engines. As this alloy is not too expensive, it is possible that the simpler method of manufacture will make this one-piece bearing most economical.

---

* Superior number refers to a specific reference listed at the end of this subsection.

The metallic lining or shell does not support the shaft directly when running; only during prolonged periods of rest does the shaft come in metallic contact with the lining. Since this condition usually exists when the machine is started from rest, the frictional resistance is high, and the wear on the lining may be excessive. During running, the shaft is supported on an oil film which, depending upon the design and the dimensions of the bearing, as well as the type of oil and the means for its circulation, may vary from only microscopic thickness to several thousandths of an inch. It may also exert considerable hydrodynamic pressure on the shaft, sufficient actually to support the shaft and whatever load the shaft may carry. The friction loss in the properly lubricated bearing is purely the result of fluid shear in the oil film, and the magnitude of the loss depends upon (1) the area of shear, (2) the rate of shear, which increases with increased velocity and decreases with increased film thickness, and (3) the viscosity of the lubricant. In properly designed and lubricated bearings, the friction loss when running is of relatively small order.

In this class are included all bearings known as slide or glider bearings for both radial and axial or thrust loading. Best known of these bearings are perhaps the Kingsbury thrust bearing and the closely related Michell bearing, which have found extensive use in large water wheels and turbogenerators. Simple modifications of this type of bearing are also used as thrust bearings in small high-speed vertical motors.*

Other types of cam bearings or multiple-collar bearings, sometimes made from nonmetallic materials such as rubber or plastic, although important in certain fields and applications, have found little use in electric motors.

One type of sleeve bearing which is extensively used in small electric motors is the oil-impregnated powdered-metal bearing, but applications of this bearing are limited to light-load and -duty operation, such as household appliances, small fans, etc.

Antifriction Bearings. Antifriction bearings are usually understood to be ball and roller bearings, including the needle roller type. The term "antifriction bearing" must not be construed to mean that these bearings are not subjected to the fundamental laws of friction. Owing to distortion of the rolling elements and the raceways under load, the motion is not a pure rolling motion, but includes some local sliding between balls and raceways which introduces minor frictional forces. In addition, the retainer or separator, which keeps the rolling elements distributed over the entire bearing, introduces sliding friction of appreciable magnitude, although far smaller than the frictional losses found in the average sleeve bearing.

Ball bearings of different makes and of different types have very important design features which will make one bearing differ very much from another as far as its load capacity and life are concerned. It is therefore important to select the proper bearing for each application.

As the balls are always of the same geometrical shape, the difference is usually found in the ball tracks of the two races, *e.g.*, deep-groove bearings, angular-contact bearings, double-row bearings, self-aligning bearings, etc. The assembling method and the construction of the retainer are also factors affecting the capacity and the serviceability of the bearings and must therefore be taken into account when selecting a bearing for a certain application.

Roller bearings, by virtue of greater area of contact between rollers and races, are theoretically capable of carrying heavier radial loads and are for this reason often used in heavy-duty motors like the mill and traction types. The cylindrical roller bearing, however, has very small thrust capacity, and also, as it is more apt to be noisy, particularly at high speed, it has not found much use in the industrial motor field.

---

* The Westinghouse Electric Corporation some 15 years ago, in the development of a new high-speed vertical rayon-spinning motor, made very successful use of a flexibly supported shoe thrust bearing for the lower bearing of this 10,000- to 12,000-rpm motor.

SELECTION OF PROPER BEARINGS FOR THE ELECTRIC MOTOR

The general trend is toward the use of ball bearings in the electric motor. There are many sound engineering reasons for this, but demands from the trade have to some extent accelerated the adoption of the ball bearing for this service.

The standardization of ball and roller bearings over a wide range of sizes, which permits interchangeability of different manufacturers' products and simplifies the obtaining of spare bearings for replacements, is a factor that has promoted the popularity of these bearings. The demand for ball bearings in the electric motor has steadily increased so that today the great majority of motors built are equipped with ball bearings.

The advantages of the ball bearing are many and varied, and any one of its good points may be the most important feature in a certain application. For example, the less space occupied may be of prime importance. This is often true in the machine-tool industry and marine applications. Practically no danger of oil leakage and very infrequent lubrication may be of paramount importance in another installation, *e.g.*, in the food-processing or clothing industry. Still, in another case, low friction at starting may be the most important (in dynamometers, for example), while in some other service, little or no end play may be a necessary feature.

The one outstanding feature and advantage of the ball bearing, which by itself alone would justify the important place it occupies in the electric-motor industry, is its ability to carry a heavy thrust load in addition to a radial load. It would be difficult to picture many present-day machines without the ball bearing to carry thrust in a simple and efficient manner. The electric motor is better because of this important feature of the ball bearing.

Another feature of the ball bearing which is valuable to the electric motor is its negligible wear. This feature practically guarantees no change in the rotor air gap, and thus the efficiency of the motor is maintained through its entire life. Ball-bearing wear is usually caused by dirt or by corrosion. Generally such conditions are accompanied by noise and vibration, indicating trouble. Replacement of the bearing can thus be accomplished before any damage is done to the motor.

Ball Bearings for Motors. The majority of ball bearings in use are lubricated with grease, of which there are many types with different characteristics to meet different conditions with regard to temperature, speeds, atmospheric conditions, etc. In the electric motor, grease is the ideal lubricant because of the comparative ease whereby it is introduced and retained in the bearing housing, a feature which is particularly important as most lubricating oils are detrimental to the commonly used insulating materials in the motor windings and connections.

More ball bearings fail from too much grease than from too little. More electric motors have failed from overgreasing than from insufficient lubrication, the implication being that excess grease from the bearings may be very harmful to the motor as a whole. Frequent and indiscriminate greasing subjects the bearings and also the motor to many hazards.

To remove such hazards from the most common sizes of commercial motors, the prelubricated and sealed ball bearing was introduced on certain frame sizes and for certain service by the Westinghouse Electric Corporation, and after careful study of closely kept service records from thousands of motors, the use of these bearings has now been extended to include general-purpose motors up to 75 hp at 1,800 rpm.

These bearings are now a standard product with the leading ball-bearing manufacturers and are available with different types of greases for different applications, including silicone grease for extremely high temperatures.

The life expectancy of the prelubricated bearing, without any regreasing or upkeep, is the same as for a conventional bearing receiving the best of care and lubrication.

The prelubricated and sealed bearing has proved to be a most valuable contribution toward trouble-free operation of electric motors, and as the service records become more complete, it is probable that its use will be extended to even larger motors and to cover longer life expectancy.

This bearing is equally satisfactory for vertical mounting. It probably has even greater value as an aid to trouble-free operation in such applications, inasmuch as an excess of grease in the upper bearing of a vertical motor more readily finds its way down onto the motor winding than the excess from a horizontally mounted bearing.

The physical dimensions of available prelubricated and sealed bearings correspond to both the single- and double-row widths of both the light and medium series. The ball complement, however, is the same as in the single-row bearing. It is quite possible that regular-width double-row bearings with seals will soon be available.

Ball-bearing Mountings. The simplest mounting is obtained when end thrust is taken in one direction only by each bearing (see Fig. 14-131). This mounting is preferred wherever a small amount of end play is permissible so that no binding may occur from end to end; such binding may easily load the bearings to destruction. The end play must provide for the aggregation of all machining tolerances in the component parts of the assembly, plus any difference in expansion between the shaft and the stationary assembly. Such expansion depends upon how the motor is ventilated and how high the total temperature may go. For every 12 in. of distance between bearings, 0.003 in. should be allowed.

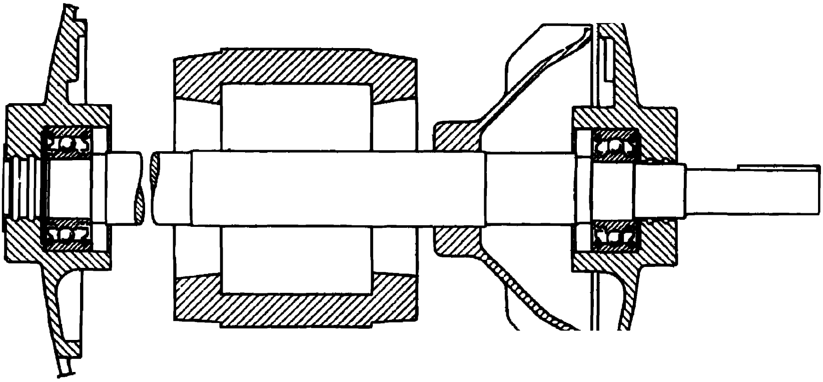

FIG. 14-131. Ball-bearing assembly. Slight end play lets either bearing take thrust load, depending upon the direction of thrust.

If the end play in a particular motor must be less than the minimum obtained by satisfying the conditions outlined, any end play in excess of what is necessary for unrestricted expansion of the shaft may be taken out by installing shimming washers behind the outer race of the one or both bearings.

If no end play is permitted outside the internal looseness in the bearings, the bearing at the shaft-extension end is locked on the shaft by a nut clamping the inner race against a shoulder of the shaft, while the outer race of the same bearing is clamped between a shoulder in the bore of the bearing housing and a suitable step cap over the housing (see Fig. 14-132). The bearing at the opposite end must be made to float in its housing to allow free expansion of the shaft.

In applications where no end play can be tolerated, special bearings with no internal looseness are furnished by most manufacturers. The standard double-row bearing is, for practical purposes, free of internal looseness in the axial direction. Figures 14-133 and 14-134 show the two methods used for taking out looseness in the double-row bearing assembly. In Fig. 14-133, the grooves for the balls are spaced slightly closer in the outer race, and the resultant load components will then converge inside the bearing. In Fig. 14-134 the inner race is grooved with slightly less spacing than the outer race, and the resultant load components will be directed to converge outside the bearing. The former method is preferred in the electric motor as this bearing has some angular flexibility, permitting slight deflection in the shaft. The mounting of preloaded bearings requires very accurate machining and line-up of the parts, as even slight misalignment will impose excessive loads on the bearings.

Wear in a ball bearing is of such small magnitude that the air gap in the motor can be considered permanently uniform, provided that the shaft is made rigid enough not to deflect too much under the combined weight of the rotor and the bending moments of all external shaft loads, plus any unbalanced magnetic loads acting on the rotor. As the efficiency of most types of motors is adversely affected by nonuniformity of the air gap, the shaft is designed to withstand these forces with little deflection, and consequently there is no need for self-aligning bearings in the standard electric motor. The self-aligning ball bearing has very low thrust capacity as compared to the rigid ball bearing and is for this reason not a suitable bearing for the general-purpose motor.

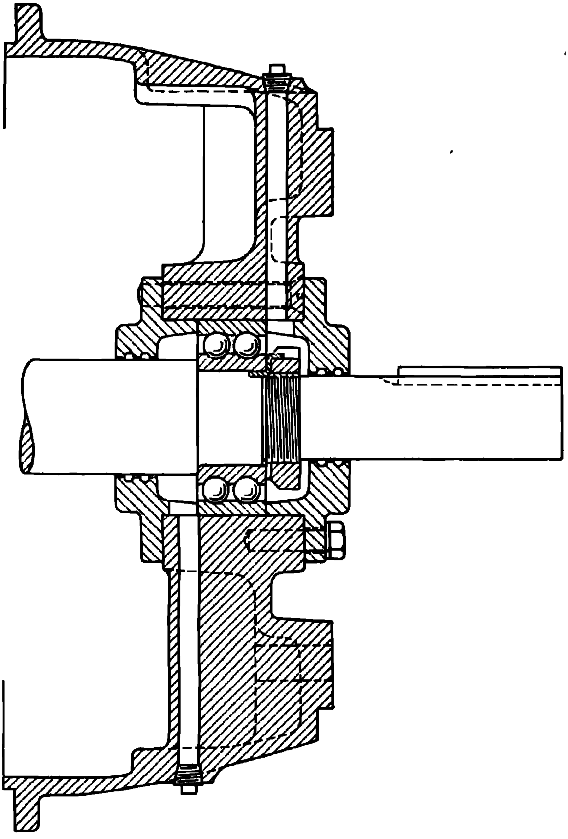

FIG. 14-132. Ball-bearing assembly. Axial locking of the bearing at the driving end permits accurate line-up of rotating load.

Motors with vertical mounting and hollow shafts, primarily for pump service, are manufactured in standard series by the leading electric-motor manufacturers. These motors are designed for heavy thrust loads. The top bearing usually takes the thrust and may be required to take thrust in both directions; the lower bearing is a guide bearing.

Since the shaft is made hollow to admit the pump shaft to the clutch on the top of the motor, the bearings become quite large, and in the larger ratings the relatively high speed attained by the balls and their retainers introduces a problem of lubrication. It has been found that, where the speed is very high, grease, particularly if there is an excess, will exert a drag on the fast-moving balls, therefore generating considerable heat which is harmful to both bearing and motor.

In one particular case of failure of a large 3,600-rpm horizontal machine, it was found that the heat generated in the grease-lubricated bearing had expanded the outer race until the bearing could not float and yield to the axial expansion of the shaft. The thrust load resulted in failure of both bearings.

The problem of heat generated in the grease can be minimized considerably by not using more grease than necessary and by providing a grease overflow so that repeated refillings cannot build up grease under pressure.

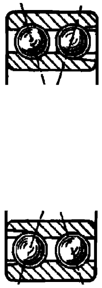

Fig. 14-133.

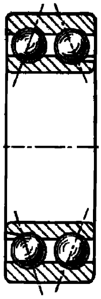

Fig. 14-134.

Figs. 14-133 and 14-134. Direction of load components in double-row bearings with no end play.

The speed limits for grease lubrication are discussed by R. K. Allen in his book, "Rolling Bearings."[1] The speed of grease lubrication in ball bearings is limited by the formula:

$$d \times N \leqq \frac{300{,}000}{}$$

where d = the diameter of the bore in the ball bearing in millimeters, and N = rpm of the shaft.

Example: What is the maximum rpm for a grease-lubricated ball bearing of the 320 size? d = 100 mm.

$$100 \times N \leqq \frac{300{,}000}{\sqrt{100/50}}$$

Hence

$$N \leqq \frac{300{,}000}{100\sqrt{2}} \leqq 2{,}100 \text{ rpm}$$

This formula is useful only as a guide, and it may have to be revised from time to time because of new and improved materials and designs. The factors likely to cause changes in this formula are improvements or developments in the greases and possibly new types of ball retainers. Other factors that may affect present concepts of maximum speed of the bearings are superfinish of the surfaces and demands for higher speeds, even at the cost of shorter life.

Regardless of how the limit of speed for grease-lubricated bearings is established, experience has shown that, for very high speeds, oil lubrication is more satisfactory. No doubt there is a wide region at moderate speeds where either system may be used successfully, so the designer may have his choice, but as the oil-lubricated bearing is very important, some of the designs that have been used in the electric motor will be discussed.

The problem of supplying the right amount of oil at all times to the bearing without risk of oil leakage has led to a number of more or less complicated designs or systems. The quantity of oil required in the ball bearing is very small; an oil mist is sufficient, but if such mist is generated in the bearing housing by agitation, the quantity is difficult to control. The mist formation depends partly upon the viscosity of the oil, and as the viscosity is a function of temperature, which varies considerably

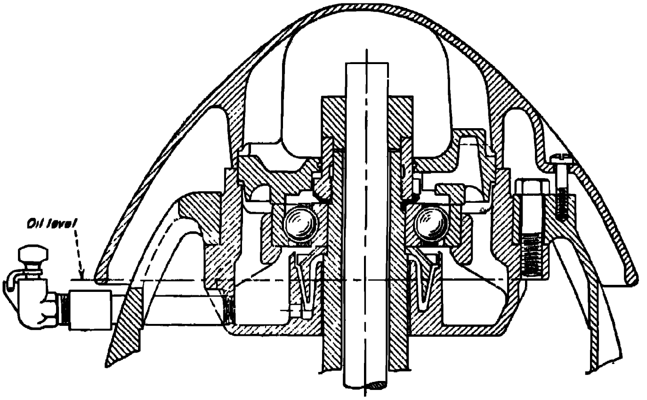

Fig. 14-135. Downward-thrust bearing in vertical hollow-shaft pump motor.

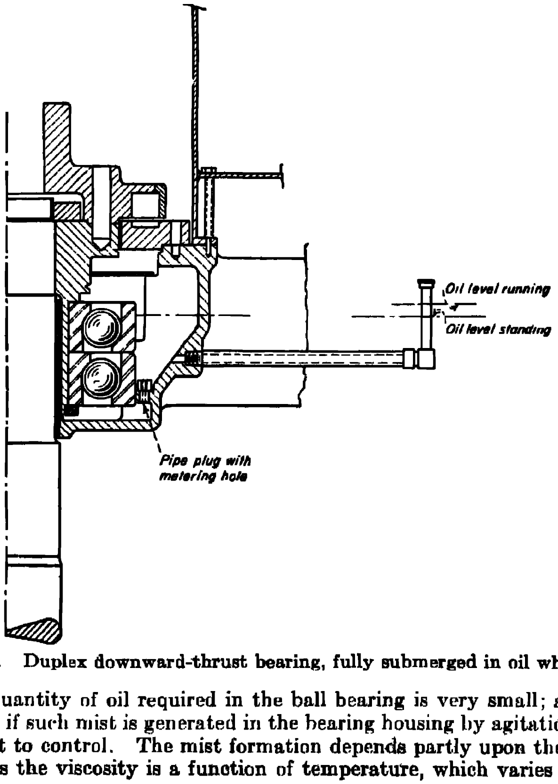

Fig. 14-136. Duplex downward-thrust bearing, fully submerged in oil while at rest.

from the condition at start and until the maximum temperature is reached, the bearing might be starved for oil or may be flooded as the temperature changes.

With this type of oil lubrication the bearing is started up from rest in a more or less dry condition, and if the rest periods are prolonged, as in the case of stand-by machines, corrosion may become a problem in the dry bearing. Atomization of the oil by means of compressed air is more positive and easier to control, but such systems become complicated and expensive for individual machines. Condensation of vapors in the air may be difficult to extract, and water is detrimental to proper lubrication.

A design that has proved reliable and satisfactory in large vertical hollow-shaft motors and at the same time is simple enough to be practical is shown by Fig. 14-135. The objection raised above with regard to danger of corrosion is possibly its greatest fault. Another objection from the manufacturing standpoint is that, if the same frame and bearing assembly is used for machines of different speeds, the tapered collar which pumps the oil to the bearing, as well as the surrounding walls of the oil reservoir, must be changed to correspond with the change in speed.

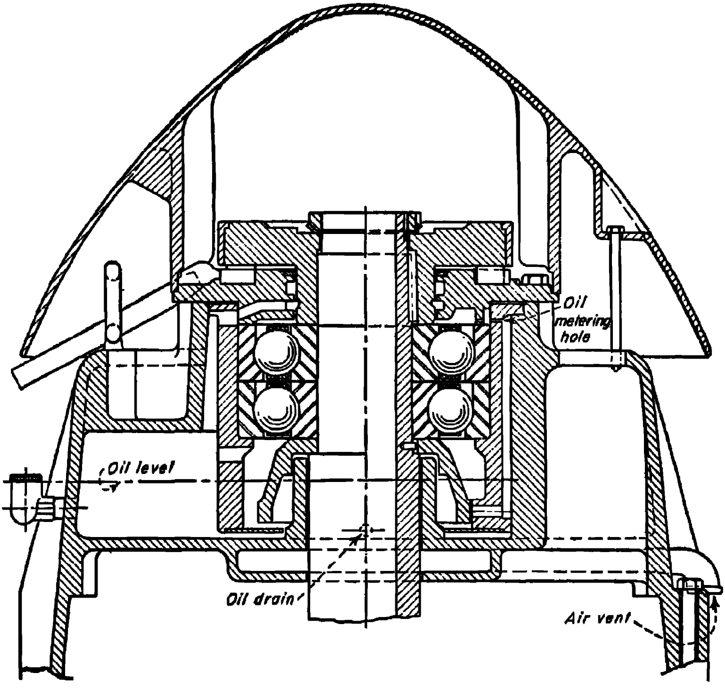

FIG. 14-137. Duplex downward-thrust bearing, lubricated during running by trickle feed.

A better method, which has found extensive use in large vertical machines but also lends itself to industrial motors, is shown by Fig. 14-136. The bearing during rest is completely or partly submerged in the oil and is thus protected from corrosion. When the motor is started, the oil is thrown out of the bearing into the annular oil reservoir surrounding the bearing. A small metering hole in a partition near the bottom of the bearing regulates the return flow to the bearing to the proper amount needed. When the motor is stopped, the metering hole equalizes the oil level, and the bearing again becomes submerged in the protective oil. This design has more flexibility for different speeds of the motor, as the size of the metering hole is the only detail that requires change. A similar method can also be used for horizontal mountings, but as the highest oil level must be well below the shaft to prevent oil leakage along the shaft, only the lowest part of the bearing, including the balls at the bottom, can be submerged in oil during rest.

A variation of a nonsubmerged bearing is shown by Fig. 14-137. The oil is pumped by a revolving collar through vertical ducts to the top of the bearing, where small metering holes admit a small quantity of oil to trickle down through the bearing. This design will also permit different speeds with simple alterations of the parts.

Figure 14-138 shows a horizontally mounted bearing with oil lubrication, where the oil is delivered to the bearing by an oil ring. This method works satisfactorily where the speed of the shaft is not extremely high.

Ball-bearing Assembly. The following points should be observed in mounting prelubricated and sealed ball bearings in electric motors:

The bearings are mounted by pressing the bearing onto the shaft against an interference fit of about 0.0005 in. per in. of shaft diameter. The mounting is preferably made by pressing on the inner race, using a tubular square-ended tool, which is guided so that it cannot exert pressure on the ball retainer or outer race. The prelubricated bearing does not lend itself to mounting by a shrinking-on method, as the heat required for expansion may injure the sealed-in lubricant or the seals of the bearing. The final location of the bearing is determined by a shoulder of less height than the radial thickness of the inner race. The shoulder height is limited to be less than the height of the inner race in order to provide a grip or a hold for a bearing puller by which the bearing may be pulled off without injury.

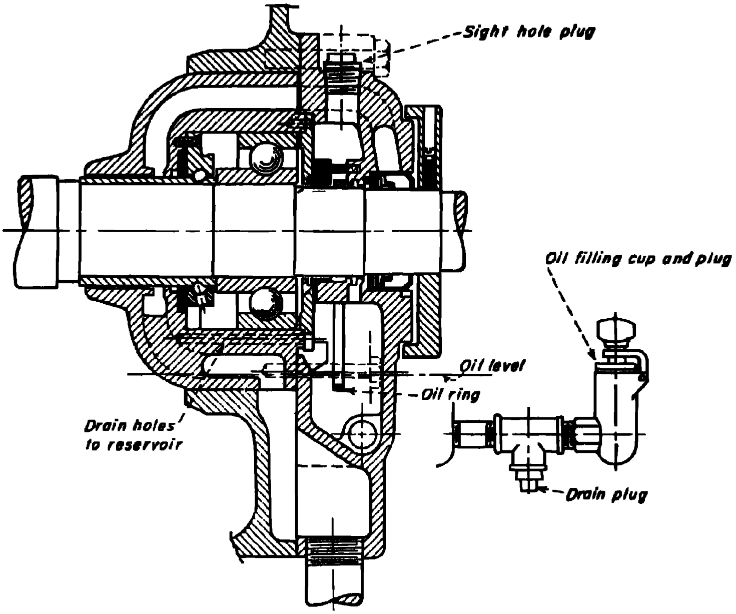

FIG. 14-138. Oil-ring-lubricated ball bearing in horizontal machine.

The bore in the bracket housing is made to give a close fit around the bearing but without actual interference. Owing to the close fit, there is a tendency for the bracket to cock and bind if it is not entered and pushed on absolutely square. Such binding should be overcome by tapping the bracket lightly near the center of the bearing housing. Repeated cocking by hard blows at the rim must be avoided, as this may permanently distort the bearing races by brinelling.

The safest way to remove the bracket is to use a suitable puller, which engages in two diametrically located boltholes, and a jackscrew against the end of the shaft.

For similar reasons of protecting the bearings from injurious shocks prior to putting the motor in service, care should be taken when mounting pulleys or other power take-offs on the shaft extension that no heavy blows are struck in the axial direction. Any such mounting should be made by light tapping with a mallet or with suitable press tools. If heavy pounding is necessary, the fit is too tight and should be relieved to where light tapping is sufficient.

Sleeve Bearings. The sleeve bearing is still a very important part of present-day machine design and deserves full consideration in any discussion of bearings and choice of bearings for electric motors.

The one outstanding advantage of the sleeve bearing, which is entirely lacking in the ball bearing and which is of great value in the assembly of, for example, motor-generator sets, is the fact that it may be made split, permitting assemblies which otherwise could not be made or would involve complicated design. Another advantage of the sleeve bearing in electric-motor applications is that the cushioning and damping effect of the oil film tends to make the motor run very smoothly and quietly, which, at high speed in particular, usually makes the sleeve-bearing motor the better performer. Some users prefer the sleeve bearing because it is comparatively easy to repair after a burnout, and thus it may not be necessary to carry spare bearings.

In case of a complete bearing failure, however, extensive damage may be done to the rest of the machine. In the electric motor, the windings and the shaft are almost certain to become damaged in case of a sleeve-bearing burnout, and therefore not too much weight should be placed on easy repair of the bearing. It is better to choose a bearing which will not cause extensive damage in case of a failure.

The sleeve bearing, because of its loose fit over the shaft journal (the looseness is usually 0.001 per in. of diameter and is never less than 0.002 for journals over 1 in. in diameter), permits easy assembling of the end bells to the frame. In this connection the end bell should be turned upside down while pushing it over the shaft so that the oil ring does not interfere with the entry of the bearing over the shaft. Even mild attempts to force the bearing on the shaft if the oil ring is interfering may distort the oil ring so that it fails to revolve freely with the shaft. The result will generally be a bearing failure.

The thrust capacity for continuous load is very small in the average sleeve bearing, yet the ability to take axial shocks at standstill is ordinarily greater than in corresponding size ball bearings. Therefore there is less danger of doing injury to the bearing in mounting pulleys or couplings on motors equipped with sleeve bearings.

Foreign matter is destructive to all bearings, and provisions must be made in the mounting to exclude gritty dust as completely as possible. If foreign matter, regardless of all precautions, enters the interior of a sleeve bearing, the danger of damage is usually less than if it enters a ball bearing. In the sleeve bearing, foreign matter is often carried away with the oil and may settle out in the bottom of the oil reservoir where it is harmless. If abrasive material lodges in the babbitt, it may score the hardest journal to destruction with no indication other than a rise in the temperature of the bearing. This may not be detected until after the damage is complete.

Usually the end play of the rotor is made considerably larger in sleeve-bearing motors than in those equipped with ball bearings. The reason for this is that the thrust capacity of the sleeve bearing is so small that even the thrust caused by imperfect alignment of the magnetic and mechanical centers may be too much for the bearings. Liberal end play will permit these centers to line up automatically, and the end thrust is thus reduced. It is claimed that end play is occasionally beneficial because of less tendency for brushes on commutators or collectors to wear grooves which may cause binding and sparking. It is probably also beneficial for the distribution of oil in the bearing. There is, however, danger of pumping action which may cause leakage of oil from the bearing, and it can increase the wear of the seals.

The most common means for supplying oil to the sleeve bearing is by an oil ring which revolves with the journal, lifting oil from the oil reservoir below and depositing it on the journal at the top of the bearing through a suitable slot. The oil is distributed over the full length of the bearing by grooves provided in the lining, and the rotation of the journal builds up a high-pressure oil film on which the journal floats with very little frictional resistance. This is the ideal condition which should prevail in all bearings having full fluid lubrication, and when it exists, good performance results. Unfortunately, the ideal is not always attained, and in the electric motor there are many instances or reasons why the ideal cannot be obtained. The most obvious of these reasons is that, in case of an external load in form of a belt or gear drive, the direction of the load may be anywhere around the 360 deg of the bearing. Therefore the oil grooves, which should not extend through the high-pressure area (which is approximately the loaded side), may be at the wrong location and thus oppose the build-up of a high-pressure film in that area.

Another reason why the sleeve bearing in the electric motor may not always work under the best conditions is the fact that the electric motor, because of its versatility, often is operating on a cycle with frequent starts and stops. At every start it takes a few revolutions to build up the oil film. In the meantime, the friction and wear are high. If the side load is high and remains during shutdown, as, for example, the load from initial belt tension, the oil is rapidly squeezed out from the loaded side, and even a short shutdown period will cause the bearing to start more or less dry. The ideal application for a sleeve bearing is where the machine is running for long periods of time without shutdowns. For frequent stops and starts the ball bearing will prove more satisfactory, not only because of less bearing troubles, but the lower bearing friction tends to reduce the starting time. As mentioned, the sleeve bearings of the electric motor are usually lined with soft babbitt to accommodate shaft deflection inside the bearing. The longer the bearing is, the more the shaft will deflect, and the more there is need for such flexibility of the bearing lining. The length of the sleeve bearing used in electric motors in the past has been rather great: 2 to 2½ times and even 3 times the shaft diameter. Usually the bearing load, when figured as evenly distributed over the projected area or length times diameter, has been limited not to exceed 100 psi, depending upon the velocity of the journal. There has been a tendency recently to shorten the length and consequently, of necessity, to increase the unit loading, but no radical changes, as, for example, attempts to meet the dimensions of the ball bearings, have as yet been made in sleeve bearings for electric motors.

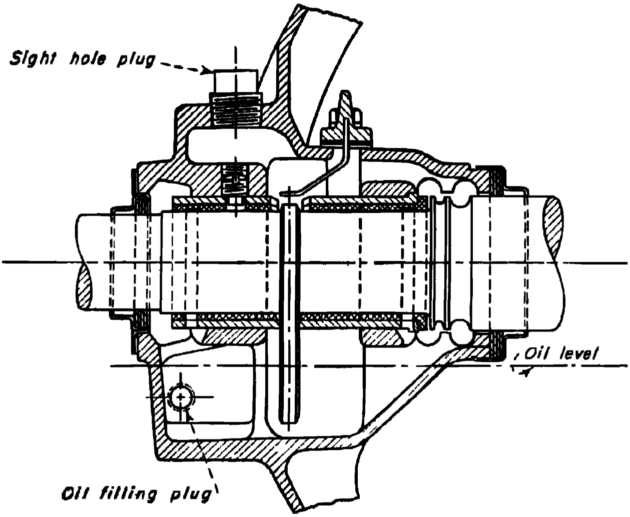

FIG. 14-139. Sleeve bearing with oil-ring lubrication and felt seals around the shaft.

Figures 14-139 and 14-140 show two typical sleeve bearings with oil-ring lubrication. Figure 14-140 is made with an air by-pass which equalizes the air pressure inside and outside the motor and thus prevents air from passing through the bearing, cutting down the oil leakage.

Oil-ring-lubricated bearings should not be used where the journal velocity exceeds 1,800 fpm. For higher speeds, forced lubrication, preferably with cooling of the oil, should be used. For very low journal speeds, a chain will carry more oil to the bearing than an oil ring and is therefore often used for such cases.

Waste-packed bearings are used in many places where speeds are not too high and the load is light, but this type of oiling is not used extensively in general-purpose motors.

It is possible that future developments in the field of superfinish of both journals and bearings will permit very thin oil films (boundary lubrication) to separate effectively the metallic surfaces at very much higher pressures than have been considered safe so far and thus bring about a revival of the sleeve bearing better to fit the present needs.

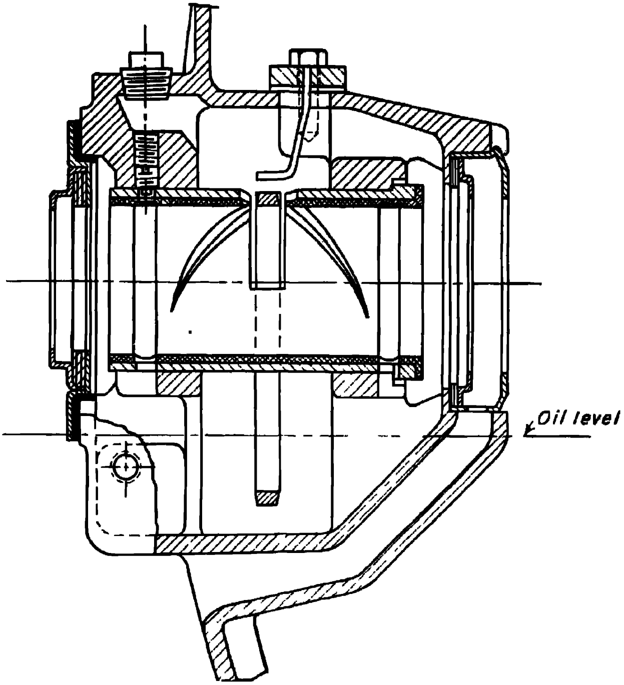

FIG. 14-140. Sealed-sleeve bearing with air by-pass.

MOTOR BEARING MAINTENANCE

The time is past when the oiler's work was classified or rated with the floor sweepers. With the high cost of shutdowns for repairs, the oiler's work has become very important and requires a high-class man properly trained for the work. The oiler should be trained to recognize signs of weakness in the bearings, such as small but unjustified temperature rise, different noises, vibrations, and appearance of the oil which may indicate oxidation or rise in acidity, and should make reports regarding these symptoms. In this way, bearings can be prevented from failing at the most critical moments of production, thus saving considerable expense. In general, the recommendations for oil and grease as given by the motor manufacturer should be followed. For special conditions (usually atmospheric), the user can, if careful performance records are kept, find more suitable lubricants for his particular conditions. The oiler should be capable of keeping such records.

The most important characteristics required of the oil for the lubrication of sleeve bearings are

1. Correct viscosity to assure best distribution of fluid-film formation for the existing operating conditions of speed, load, and temperature
2. High chemical stability in order to resist oxidation and the formation of sludge or soapy deposits
3. High film strength to minimize friction and film breakdown where boundary conditions exist
4. Ability to resist mixing with water and forming emulsions

Good grease for antifriction bearings should have

1. High chemical stability, resisting oxidation and formation of nonlubricating or corrosive products
2. Maximum resistance to separation of the oil from the soap base
3. Correct consistency at operating temperature to form protective films, minimize leakage, and reduce power loss and heat generation to a minimum

The most common cause for failure of motor bearings is the unduly tightened belt. The belt man, knowing that the new belt will stretch, installs it extremely tight. The operators of the driven machine will usually keep the belt tighter than the horsepower rating of the motor requires, particularly if heavy peak loads are a characteristic of the drive. In such cases, an oiler can prevent trouble if he is capable of judging needed belt tension.

II. Angular-contact ball bearings
III. Double-row ball bearings
IV. Self-aligning ball bearings
V. Ball thrust bearings

EDITOR'S NOTE

Antifriction bearings are now universally applied to every sort of plant and production equipment. It is important, therefore, that plant engineers and supervisors be reasonably well acquainted with the various types and their functional characteristics in order that they may use them intelligently. Inasmuch as plant supervision is seldom concerned with the initial selection of bearings for an original application, the procedure involved in such selection is omitted. Where such guidance is required, however, it may be obtained from bearing manufacturers' catalogues or by consultation with bearing engineers.

The concern of plant supervision is mainly with bearing maintenance. This is treated in detail under the heading of Antifriction Bearing Fundamentals. A secondary consideration is the understanding of the construction and functioning of the various types of bearings, which are covered in subsections Cylindrical and Needle Roller Bearings, The Tapered Roller Bearing, Self-aligning Roller Bearings, and Ball Bearings.

For a comprehensive treatment of the subject of antifriction bearings see the bibliography at the end of this section. For application data see manufacturers' catalogues and application handbooks.

ANTIFRICTION BEARING FUNDAMENTALS

BY BRYCE RULEY AND JOHN C. MORGAN

Senior Engineer, SKF Industries, Inc.
Engineer, Hyatt Bearings Division, General Motors Corporation

Antifriction or rolling bearings are used primarily to reduce the friction between stationary and moving machine parts. Fundamentally they are superior to plain or sliding bearings because they have a much lower coefficient of friction, and their starting friction is not much greater than the running friction.

Antifriction bearings are either of the ball or roller type. Functionally they are designed to carry either pure radial or pure thrust loads or a combination of both.

Most ball and roller bearings are made up of an outer ring, an inner ring, and a set of rolling elements, balls or rollers, spaced by a cage or separator. The rolling elements are the most important since they transmit the loads from the moving parts of the machine to the stationary supports. Balls are, of course, uniformly spherical in form, but rollers may be straight cylinders, or they may be barrel- or cone- (tapered) shaped, or other forms, depending on the purpose of the design and the inventiveness of the bearing designer. The rings supply smooth, hard, accurate surfaces for the balls or rollers to roll on, while the cage or separator keeps them properly spaced circumferentially. Some types of ball and roller bearings are made without separators, and some types of roller bearings are made with only the inner or outer ring, the rollers operating directly upon a suitably hardened and ground shaft or housing.

BEARING LIFE

The individual requirements of an application and the character of the load dictate the choice of bearing type; the size of the bearing depends on the magnitude of the load. Bearings are rated according to the loads they are able to carry and the length of time they can carry such loads at certain speeds. A unique feature of antifriction bearings is that their useful life is not determined by wear but by fatigue of the operating surfaces under the repeated stresses of normal operation. Fatigue failure, which occurs as a progressive flaking or pitting of the surfaces of the raceways and rolling elements, is accepted as the basic reason for the termination of the useful life of a bearing, since all other types of failures are usually regarded as preventable.

Since the load on a bearing determines the severity of the stress on the bearing parts, it follows that, if the load is increased, the life of the bearing will be decreased, and, conversely, if the load is decreased, the life of the bearing will be increased. This relation is expressed by the equation

$$\text{Life} \propto \frac{1}{\text{load}^3}$$

Thus, if the load on a given bearing is doubled, the life expectancy is reduced to one-eighth its former value.

The life of a bearing under a given load will, therefore, be a certain number of revolutions. If this number of revolutions is used up at a relatively high rate, the life of the bearing will be correspondingly short. If the total number of revolutions is used up at a low rate, the life of the bearing will be correspondingly longer. The relation between life and speed is, therefore, expressed by the equation

$$\text{Life} \propto \frac{1}{\text{speed}}$$

All bearing-rating tables are based on extensive laboratory tests. When a number of apparently identical bearings are run to fatigue failure under a given load, a considerable dispersion is found in the individual bearing lives. This dispersion is shown by Fig. 15-1. Since the *median life* (life at which 50 per cent of the bearings have failed) or the *average life* (usually considered the life at which 60 per cent of the bearings have failed) are the most easily and accurately found, many bearing companies give their load ratings for some median or average life. This is usually given as so many hours median (or average) life at a certain speed in rpm. Other companies give their ratings in terms of the 10 *per cent failure* point, accentuating the importance of reliability in bearing applications. A rough comparison can be made between bearings rated by different methods by the rule that average life is four to five times 10 per cent failure life.

Since laboratory tests of bearings are made under good operating conditions, some allowance must be made when operating conditions in applications are unusual or unfavorable. The original designer has usually provided for this by the use of a "service factor" based on his own practical experience or on the experience and advice of bearing engineers.

Many types of bearings can carry both radial and thrust loads. For a radial bearing that can do this, the combined load is usually transformed into an equivalent radial load, *i.e.*, a pure radial load, for which the bearing would have the same life as under the actual combined load imposed. Similarly, for those few types of thrust bearings which can carry combined loads, the actual load is transformed into an equivalent thrust load. Since the method of combining loads depends to a considerable extent on the internal design of the bearings and the method of mounting them, the reader is referred to manufacturers' catalogues for specific formulas.

The capacity of a bearing as indicated by its catalogue rating in terms of life and load can be realized only if it is properly applied and properly protected by adequate seals and good lubrication.

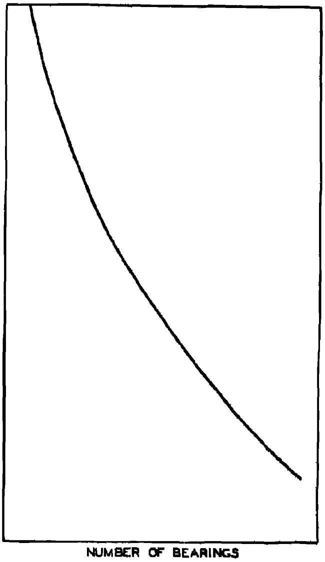

Fig. 15-1. Life dispersion.

LIMITING SPEEDS

One feature of bearing-rating tables is that they indicate limiting speeds above which the bearing will not operate satisfactorily. The designer is aware of this, of course, and gives it proper weight in the original selection of a bearing for a given application. The speed limits cannot be sharply defined since they depend on the type of bearing, the type of cage, and on the type and effectiveness of the lubrication. In general, catalogue limits should not be exceeded without consultation with bearing engineers.

LUBRICATION

The lubricant has four important functions in an antifriction bearing:

1. Lubrication of the surfaces of the bearing where sliding may occur. These are the contacting areas between the rolling elements and the cages or separators, between rollers and guide flanges, and between the rolling elements and raceways.
2. Prevent rust and corrosion by protecting the surfaces of the rolling elements and raceways.
3. Conduct heat away from the bearing and from one bearing part to another.
4. Seal out dirt and other corrosive or abrasive materials.

In low-speed applications, the lubricant may be either grease or oil. If grease is used, it should be chosen for proper consistency at the operating temperature of the bearing, and the bearing housing should be filled about half full, *never more than two-thirds full.* Oil-bath lubrication can be used for low and moderate speeds. The oil should have a viscosity of at least 70 sec Saybolt at the operating temperature, and *the oil level should be approximately even with the center of the lowermost ball or roller when the bearing is stationary.*

At high speeds circulating oil is usually necessary. This involves removing the oil from the bearing, circulating it through a cooling section, and returning it to the bearing.

In general, for any given application, the best practice is to follow the manufacturer's instructions both as to the type of lubricant and means and frequency of application.

SEALS AND CLOSURES

Since there is relative motion between the shaft and housing, some method must be used to seal in the lubricant and keep out dirt and moisture. This is the function of the seal. The seal may be an integral part of the bearing where the bearing can carry a sufficient lubricant for its operating life, or it may be a part of the housing itself. Although seals come in a wide variety of types, they may be divided into three general classes: plate seals, friction seals, and labyrinth seals.

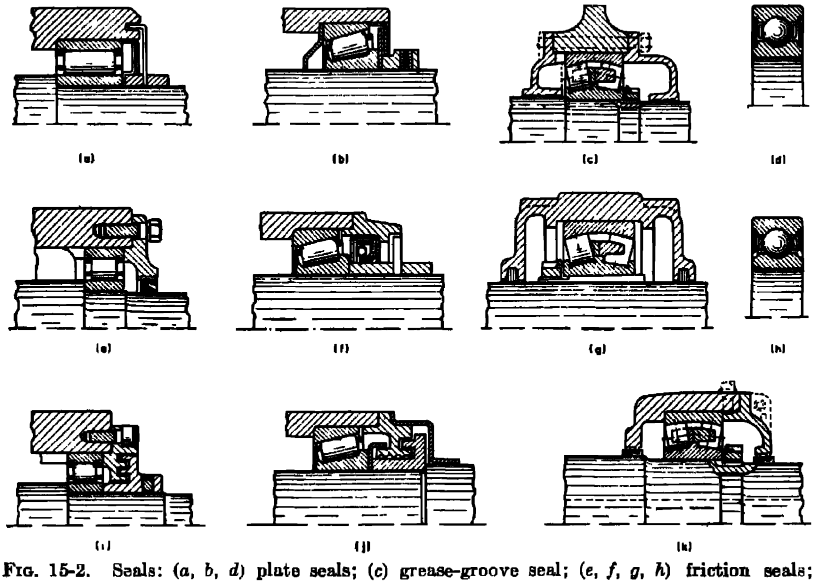

Fig. 15-2. Seals: (*a*, *b*, *d*) plate seals; (*c*) grease-groove seal; (*e*, *f*, *g*, *h*) friction seals; (*i*, *j*, *k*) labyrinth seals.

Plate seals are used with small ball bearings and grease lubrication when the operating conditions are not very severe. The dust plate is usually pressed tightly into a groove in the outer ring and comes close to but does not contact the inner race. The plate tends to keep the grease in the bearing and gives some protection against the entrance of foreign material. This seal is frictionless.

When the operating conditions are more severe, *e.g.*, when dust or abrasive materials are present, a more effective seal is required. One such seal consists of a felt ring held between two plates and pressing against a groove on the inner ring. This is, of course, a friction seal. It is much more effective in excluding dust and in retaining the lubricant but tends to increase the total friction of the bearing installation. Variations of this seal are made with rubber and synthetic materials used in place of felt.

A type of friction seal in common use consists of a felt ring which is mounted in a groove in the bore of the housing end cover and presses against the shaft surface. This is a rather effective seal when new and properly made but tends to lose some of its effectiveness after running some time since no elastic force acts to keep the felt pressed against the shaft.

Other friction seals have been designed which remedy this defect to a greater or lesser degree. A leather cuff has some elasticity so that the efficiency of the seal does not decrease very rapidly. This may be further increased by inserting a circular spring between two plates so that it gives an elastic pressure which holds the leather against the plate. Various other materials may be used in place of leather.

Labyrinth seals consist of two closely fitting rings which have a tortuous circular passage between them. One ring is mounted on the shaft and turns with it, while the other ring is integral with the housing. This seal is frictionless but is somewhat more expensive than some other types of seals.

Plate seals are used for grease lubrication only. Felt and other types of friction seals are used for both grease and oil lubrication, although felt seals for oil lubrication are usually used in conjunction with some other type of seal. Labyrinth seals are used for both grease and oil and usually are of special design to suit the operating conditions (see Fig. 15-2).

SHAFT AND HOUSING FITS

Ball and roller bearings are usually installed with either the inner ring or the outer ring a tight or interference fit. Practices vary so widely, however, depending on the type of application, the type of bearing, and the character of the load, that new application should be made only with the advice and direction of bearing engineers. Existing applications are generally supplied with instruction manuals which cover this phase of bearing practice in specific detail.

BEARING REMOVAL

Inasmuch as bearings may be applied as nonseparable units, or they may be separable so that either the outer ring or inner ring can be handled independently, it is important that the application be studied carefully to make sure that the force required to remove a bearing is applied to the proper, *i.e.*, the *tightly fitted*, part. Cleanliness is essential, of course, and the housing and machine parts adjacent to the bearing should be thoroughly clean. Proper care should also be exercised to avoid damage to the bearing in the process of removal.

The arbor press is perhaps the best means of applying the force necessary to remove bearings or individual bearing rings from shafts or housings. Regardless of the means used, however, it is absolutely essential that the driving force be directed through the tightly fitted ring.

Generally, when a piece of equipment is taken apart, the bearings stay with the member to which they are tightly fitted. Consequently, to remove a bearing, the pull or pressure should be exerted only on the tight member and so applied that it comes off straight and square, thus avoiding possible damage to both the bearing and the shaft or housing. It is important also that the force be applied only to the rings so that bearing seals or shields and separators or cages will not be damaged in the process. In the case of bearings that are made with all three major components (outer ring, inner ring, and rolling elements) separable, both rings may often be a tight fit. Then each tightly fitted ring must be removed separately, taking the usual care to avoid loading other bearing parts.

Bearing pullers are also a useful and convenient means of removing bearings and bearing rings. Driving bearings off with a hammer is the least desirable method although perhaps the one most commonly used. It is extremely hazardous, but where there is no alternative, the following rules should be observed:

1. Mount the shaft or housing in a vise wherever possible. Use wood blocks, leather, or metal guards to protect the parts from injury by the vise jaws.

2. Avoid using wood or soft metals for driving as splinters or chips may enter the bearing.

3. Do not drive directly on rings, shields or seals, separators, or on the rolling element itself.

4. In driving use smart, quick taps rather than heavy blows. This will prevent cocking.

5. Tap alternately on opposite sides to make sure the bearing or ring will move uniformly off its seat (see Fig. 15-3).

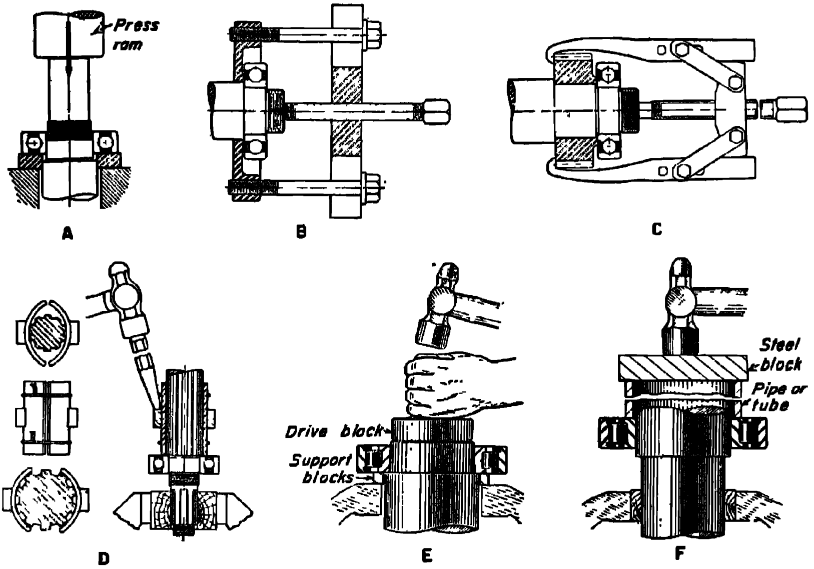

FIG. 15-3. Bearing-removal methods.

CLEANING AND INSPECTION

After the bearings are removed, they should be thoroughly cleaned and inspected to determine whether they are in proper condition for reuse.

Bearings should be placed in a metal basket and suspended in a container filled with light oil for thorough soaking. If the bearings are filled with lubricant in badly oxidized condition, they should be soaked in light oil heated to 180 to 200°F with some agitation in order to hasten the process. In case of extreme carbonization and sludging, the bearings should be soaked in a commercial solvent or in a mixture of alcohol and kerosene or safety naphtha. Only clean rags should be used for wiping and handling. Cotton waste should never be used as the short threads may get into the bearings.

A short clean bristle brush is helpful in dislodging dirt or scale from the bearing parts. Compressed air, free from condensed moisture and dirt, may also be used to blow out the bearings, but the air should never be permitted to spin the bearings as the dirt or chips present may damage the operating surfaces.

After bearings have been cleaned, they should be covered with rust-preventive compound or light oil or grease and wrapped in clean oilproof paper. If the cleaned bearings are to be reinstalled within a period up to several days, they may be left in a closed container or pan completely immersed in oil.

Before used bearings are reapplied they should be inspected carefully for damage to determine their suitability for reuse. Almost all the damage occurring to roller bearings is the result of improper handling or improper operating conditions. Only pitting or flaking may be due to natural causes as they occur when the bearing has reached the limit of its expected life.

Pitting or flaking generally appear on bearing operating surfaces that have reached the limit of their expected life, although they may also appear much earlier on surfaces stressed beyond the compressive endurance limit of the material. This phenomenon starts with the development of tiny fatigue cracks from which material fragments break loose, eventually developing craters and spreading over the entire surface of the loaded zone.

Cavities and indentations are forms of damage which are caused by the presence of dirt, chips, and even carbonized lubricants. These substances may be pressed into the roller and race operating surfaces and cause early pitting. A form of damage similar to the above but resulting from an entirely different cause and of more regular pattern occurs when bearings are subjected to vibrations or other very small movements while the bearing is stationary. This is actually a wear condition which results in markings approximating the contact area of the ball or roller and called *false brinelling*. True *brinelling* is a series of nicks or indentations on the rings corresponding to the spacing of the balls and rollers and is usually caused either during the application or removal if the driving force is permitted to travel through the rolling elements. Brinelling may also be caused by hammer blows or by the repeated application of shock loads far in excess of the bearing capacity. *Smearing* or *scoring* may be caused by careless assembly and by sliding contact between the rings and balls or rollers. *Cratering* is generally caused by electrical arcing resulting in annealing and due to rapid cooling, a rehardening of those points at which the spark occurs. There are other types of damage, of course, for which the causes are more obvious, such as *corrosion*, *cracking*, and *splitting* of rings and balls or rollers, *seizing*, and the results of the failure of cages or separators either due to wear or careless handling.

REMOUNTING BEARINGS

Before remounting the bearing in its original position, the bearing seal should be thoroughly cleaned in order to avoid scoring of the bearing rings and improper seating against shoulders, counterbores, etc. Housings should also be free from dust, dirt, and metal chips. The bearing seat and the bearing bore should be coated with lubricant to aid assembly and prevent formation of rust at the press fit. Any type of oil or grease is helpful, but best results have been obtained with lubricants containing graphite, zinc, or lead.

The pressure required to drive bearings on shafts or into housings must be applied only against the rings, never against the balls, rollers, retainers, or snap rings. As in the case of bearing removal, the pressure should be applied to the race which rotates and therefore takes the tightest fit. The pressure should be evenly distributed over the end area of the race and applied straight and square to avoid cocking which may cause scoring and possible splitting of the end ring.

Bearings may be assembled by the use of certain types of push-pullers, by arbor-press methods, and manually by the use of hammers and mallets used in conjunction with tubes and driving blocks (see Fig. 15-4).

Hammers or mallets should never be used directly on the bearing parts. The driving should be done through drive blocks or pipes or tubing faced off square and capped with a steel block or cap.

Large inner rings are usually heated in hot oil or in an electric oven to expand the bore sufficiently so that they may be shrunk in place on the shafts. Care should be taken with whatever method is used to heat the races uniformly to a temperature not exceeding 250°F. Temperatures above that may draw the temper of the races and cause soft spots rendering the race useless for further service.

In case the ring has not expanded sufficiently to slide over the bearing seat, the shaft or journal may be shrunk somewhat by packing it in dry ice. Obviously the race must be slid into position smartly as any contact with the bearing seat will result in heat transfer and consequent expansion of the shaft itself which may be rapid enough to prevent the race from being located properly.

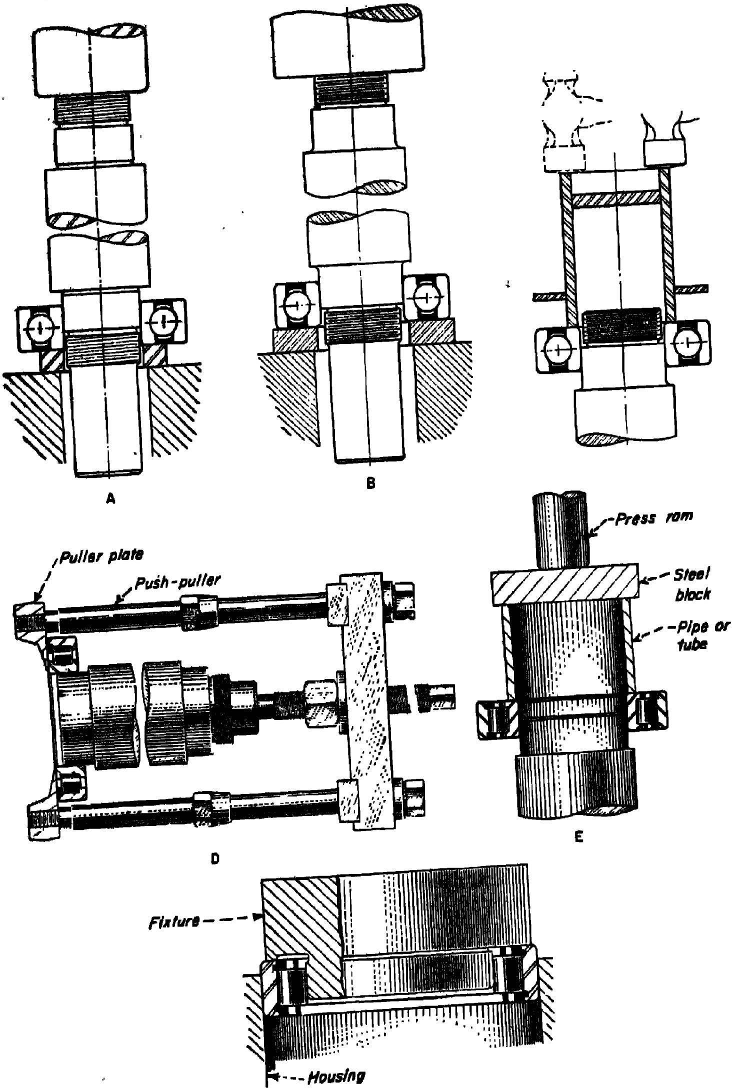

Fig. 15-4. Bearing-mounting methods.

CARE OF OTHER MACHINE ACCESSORIES ASSOCIATED WITH BEARINGS

The closure or seal used at the shaft opening should be inspected each time a bearing is serviced or replaced. Seals are designed to serve two purposes: to keep the lubricant in and to keep dirt out. They should be replaced by new seals when an examination shows that they are failing to function properly in either respect.

There are a great many types of seals, each designed for a different kind of application. One of the most common is a simple felt ring. Because they are cheap, these rings can be replaced each time the machine is overhauled. They should be replaced oftener if they show evidence of wear, scuffing, or of becoming brittle. The one-piece stamped-ring type is preferable to the split-rim type. If the method of installation requires that a split-rim washer be used, a single cut, on the bias, should be made, and care should be taken that the joint is closed properly and the washer assembled with distortion. Felt seals should be soaked in oil until thoroughly impregnated before they are installed.

Friction-type seals are used where a more positive type of closure is desired. They have as the sealing element leather, asbestos, composition, or other suitable material, usually shaped to form a wiping lip. This lip is held against the shaft at a constant pressure by means of a spring, and the whole is assembled in a steel stamping. There are many variations of this basic design, such as double seals, felt and leather, or felt and composition combinations.

The mounting of friction-type seals should be done with the greatest of care, as they are easily injured, and their effectiveness can be destroyed through mishandling. In most cases, the seal is mounted with the wiping lip toward the bearing, and since the inside diameter of the seal is less than the shaft diameter, some difficulty may be experienced in starting the seal over the end of the shaft. All sharp corners and burrs over which the seal has to travel should be removed. A tapered or bullet-shaped adaptor, recessed to fit the shaft chamfer, should be used to carry the seal over the shaft end. If keyways or splines are present, the adaptor should be extended into a thin-walled thimble which will cover the undercut section of the shaft and carry the seal to the smooth section. The seal is then mounted in the housing in the same manner and with the same care as a roller bearing. A little oil or grease should be placed on the sealing element and the shaft lubricated to assist in mounting the seal. The seal should be moved along the shaft with a twisting motion to overcome friction. A thin coat of shellac applied to the outer surface of the steel stamping will assist in making the press fit more resistant to leakage.

Gaskets are used to prevent leakage between mating flat surfaces and may also serve to adjust bearings. As they will become brittle with age and high temperature, gaskets should be renewed each time they are exposed for bearing inspection. The gasket should be fixed to one of the surfaces by a thin, even coat of shellac and permitted to dry before the parts are fastened together. Loose gasket material or frayed edges should be trimmed before assembly to prevent particles from getting into the bearing or into the lubricating system. Shims, either metallic or fibrous, should be examined with each bearing inspection. They should be cleaned and, if damaged in any manner that might affect bearing adjustment, should be replaced or repaired.

Lubrication plays such an important part in prolonging the life of roller bearings that every precaution should be taken to ensure perfect functioning of all lubricating devices. This means that all channels for the flow of oil or grease must be cleaned thoroughly, oiling devices checked, and filters renewed if necessary. With grease lubrication, the vent holes should be checked, as pressure-gun greasing may cause overlubrication. Where felts or wicks are used in lubrication, they should be cleaned or renewed as often as conditions require. Any arrangement designed to maintain a constant oil level should be checked from time to time to make sure it is functioning properly.

Keys, splines, and grinding reliefs should be cleaned carefully during any bearing inspection or replacement. Dirt becomes trapped in these recesses and corners and, when washed free by the lubricant, can become a source of bearing damage. New machine parts having keys, splines or grinding reliefs should be thoroughly washed with a petroleum solvent to remove any grinding or lapping compound that may still be present.

Threaded sections should also be carefully cleaned before assembly. The nut used on the thread should be run up before assembling the bearing on the shaft. Thus, if the threads have been improperly cut or are damaged, they can be repaired without the necessity of removing the bearing from the shaft.

Snap rings are very often used to retain bearings and races that are not secured by a heavy press fit. The snap-ring groove should be cleaned to remove all possible dirt and to ensure a firm seat for the ring. The snap ring should be ground or turned flat and be free from burrs and sharp edges. It should also be shaped so that it fits the groove snugly, not being of such diameter that it bulges or twists so as to present an uneven surface to the bearing face. The snap-ring ends should be of such design as to permit the ring to be removed easily from the application.

Washers should be flat and true to prevent distortion of the bearing when adjusting the assembly. They should be free from burrs to avoid scoring the shaft or indenting the bearing by breaking off and circulating with the lubricant. Cotter-pin holes should be cleaned with a stiff piece of wire to remove old grease and dirt. The cotter pin should be replaced after having been used once because repeated bending will weaken the legs and allow them to break while in operation.

STANDARD DIMENSIONS

Most types of bearings are made to standard dimensions so that bearings of different manufacturers have the same external dimensions and tolerances. This is true even of bearings of different types, *i.e.*, radial ball, angular-contact, self-aligning ball, and cylindrical roller types.

It must not be assumed, however, that bearings of the same type and size are necessarily interchangeable. Various other factors affect functional interchangeability. The requirement of each application dictates bearing choice, and substitutes for original equipment should be made only after careful and detailed comparison between the original and the prospective substitute.

Bearing-standardization activity is now centered in the Anti-friction Bearing Manufacturers Association (AFBMA). Needless to say, the use of ball and roller bearings conforming with standardized dimensions is beneficial to the user since it provides the advantage of alternate sources of supply, generally better delivery, and lower cost.

Tables 15-1 through 15-7*c* show the dimensions of AFBMA standard ball and roller bearings.

Table 15-1. Dimensions Metric Radial Bearings

NEEDLE ROLLER BEARINGS

Partial-revolution and oscillating-type, or relatively lightly loaded applications make wide use of the so-called "needle" bearings, with small-diameter rollers and a high ratio of roller length to roller diameter. The term "needle" was originally associated with the needlelike proportions of the roller itself (see Fig. 15-10), and bearings made up with such rollers were called "needle bearings" or "package bearings." These are also available in many types and with and without separable inner or outer rings and with and without separators. They are particularly adaptable where diametral space is limited and the advantages of an antifriction bearing are desired (see Tables 15-2*a*, 15-2*b*, and 15-2*c* for AFBMA Standard Needle Bearing sizes).

A common type of needle bearing consists of the required number of ground rollers enclosed in a hardened shell which may be open at both ends or closed on one end only. Commonly used sizes are given in Table 15-7*c*.

CYLINDRICAL ROLLER BEARINGS
AND
NEEDLE ROLLER BEARINGS

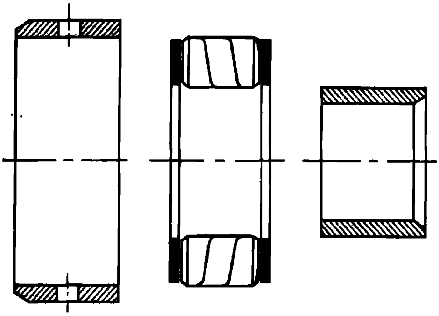
BY JOHN C. MORGAN

Engineer, Hyatt Bearings Division, General Motors Corporation

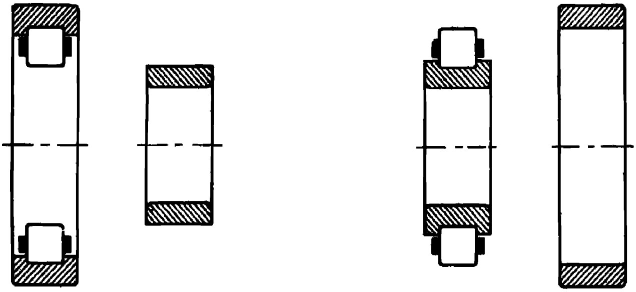
CYLINDRICAL ROLLER BEARINGS

Cylindrical roller bearings are exactly what their name signifies, *i.e.*, antifriction bearings in which the rolling elements are straight cylindrical rollers.

The rollers are usually held together and spaced circumferentially by a cage or separator, and the "roller assembly" thus formed may be entirely free of the inner and outer rings, or it may be assembled with either the inner or outer ring or with both.



Wound-roller separable roller bearing



Solid roller bearing with separable inner ring

Solid roller bearing with separable outer ring

FIG. 15-5a. Types of separable cylindrical roller bearings.

Cylindrical roller bearings are, therefore, classified according to construction, as

1. *Three-part bearings*, in which the roller assembly and both inner and outer ring are separable. This construction permits the use of the roller assembly independently of the rings or with only the inner or outer ring or with both.

2. *Two-part bearings*, in which the inner ring is separable. In this type of construction, the rollers are retained with the outer ring. The use of the inner ring is optional. It is often omitted and the rollers are operated directly upon the surface of a suitably hardened and ground shaft.

3. *Two-part bearings*, in which the outer ring is separable. In this case the rollers are retained with the inner ring. The separable outer ring may be omitted and the rollers run directly upon the surface of the housing, gear, or sheave bore, etc., suitably hardened and ground.

4. *Nonseparable bearings*. In this type both the inner and the outer ring and the rollers are assembled in such a way that the bearing can be handled only as a complete unit (see Figs. 15-5*a* and 15-5*b*).

The rollers in a nonseparable bearing may be spaced by a cage or separator, or the bearing may contain a full complement of rollers, *i.e.*, the greatest number of rollers that can be inserted between the rings with the cage or separator omitted. Usually the proportions of the rings and rollers in a full-complement bearing are such that there is very little circumferential clearance between the rollers (see Fig. 15-5*c*).

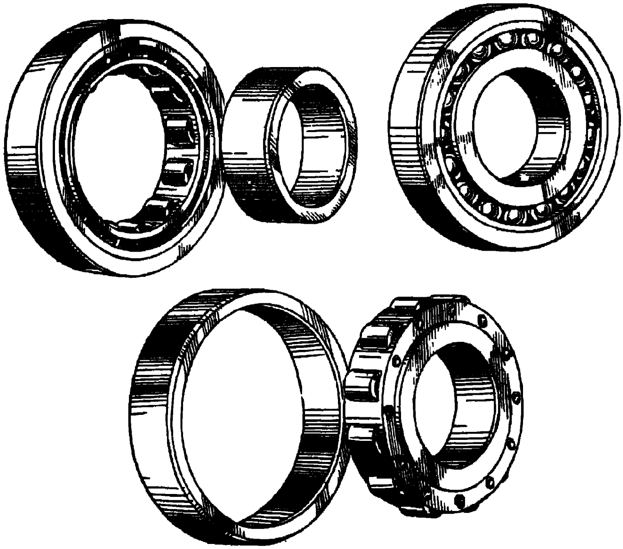


FIG 15-5*b*. Cylindrical roller bearings with separable inner and separable outer ring. Also nonseparable type with full complement of rollers.

Functionally, roller bearings may be classified as "nonlocating," "one-direction locating," and "two-direction locating." This defines their ability to locate or restrain the movement of shafts or other moving parts laterally within certain allowable limits.

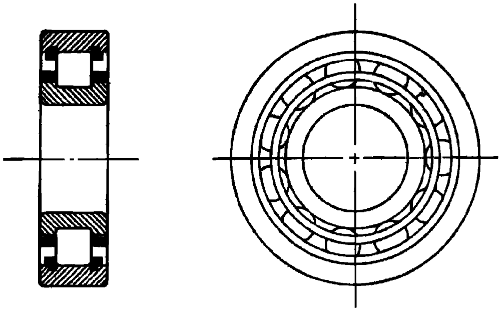
Normally cylindrical roller bearings are used for carrying radial loads only, hence the rings are plain cylinders. Adding shoulders or flanges to either or both rings increases the usefulness of the bearing, however, in that it can then be used to locate shafts or gears and even to sustain light intermittent thrust loads (see Fig. 15-6).

The great majority of applications are fitted with the so-called AFBMA standard metric-dimension bearings. These are so proportioned that the roller diameter is approximately half the bearing-section height, the other half being approximately equally divided between the inner and outer ring. The roller length is usually about the same as its diameter, hence the inappropriate but widely used term "square roller."

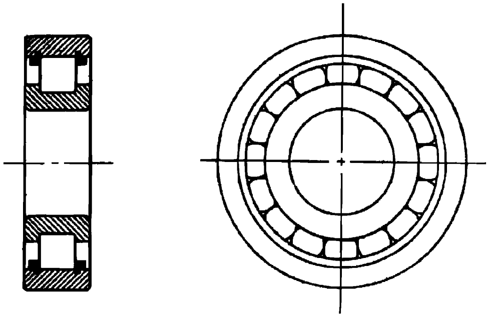
These bearings are made in several series with a wide range of sizes as shown in Table 15-1. The pattern of sizes is so arranged that several bearings, varying in width and outside diameter, are available for every given bore (see Fig. 15-7). A variety of types (Fig. 15-6) is also available in any given size to suit the requirements of any application.

Any given size may be obtained in a standard commercial grade or in a so-called "precision" grade. The former conforms with AFBMA Roller Bearing Engineers' Committee Tolerance Standard RBEC-1 and the latter with Tolerance Standard RBEC-5. The RBEC-5 grade bearings are made to closer tolerances not only on the bore and outside diameter but also on the dimensions that govern running accuracy, *i.e.*, eccentricity of the ring diameters and squareness of ring faces with ring diameters.

The running smoothness of a bearing application depends on the uniformity of the rings and rollers, the character of the finish on the operating surfaces, and on the internal diametral clearance which exists in the assembled bearing. Because of the difficulty of controlling this clearance owing to the dimensional variations of the bearing component parts and the effect of interference fits on the rings, various means have been designed to overcome these difficulties, especially for applications where internal clearance must definitely be controlled or held to a minimum.



Separator type



Full-complement type

Fig. 15-5c. Separator and full-complement-type roller bearings.

The double-row cylindrical roller bearing has been designed specifically for this purpose and is manufactured with a tapered bore (1:12) which allows the bearing to be driven up on the tapered shaft to give any desired internal clearance in the bearing. This type of bearing has the low-friction and high-limiting-speed characteristics of cylindrical roller bearings and great rigidity owing to its double-row width. It is usually made to extra-precision tolerances for machine-tool spindle and similar applications. Double-row cylindrical roller bearings with tapered bores are made with straight cylindrical outer races and can carry only radial loads (see Fig. 15-8).

A popular type of commercial bearing is the so-called "journal bearing." This is almost invariably of three-part construction, with a separable roller assembly and separable straight cylindrical outer and inner rings. These are made up with solid

rollers, with "wound" rollers, or with hollow solid rollers. They are often applied with only the outer ring or only with the inner ring, and sometimes the roller assembly is assembled alone, operating directly on the shaft and bore (see Fig. 15-9).

Journal bearings are commonly made to fractional dimensions, although there are a number of standard designs manufactured to metric dimensions on bore and outside diameter, only the widths being in inches.

On a much lower plane of quality and accuracy are the so-called "unground" cylindrical roller bearings, in which the rings and rollers are neither hardened nor finish ground.

THE TAPERED ROLLER BEARING

BY PETER C. POSS

Engineering Editor, The Timken Roller Bearing Company

FUNDAMENTAL PRINCIPLES OF DESIGN

Like many other noteworthy developments in the field of mechanics, the principle of the tapered roller bearing is remarkably simple. Essentially it consists of constructing the rolling elements, as well as the raceways, on the principle of the cone, so that lines drawn coincident with the working surfaces of the rollers and races will all meet at a common point on the axis of the bearing. This is brought out clearly in Fig. 15-11. The significance of this is at once apparent. Initially, true rolling motion is obtained, and secondly, the bearing will handle all loads, radial, thrust, or both, in any combination. Furthermore, no greater number of parts are necessary than in other types of antifriction bearings; *i.e.*, an inner raceway, an outer raceway, the tapered rollers, and the cage or roller retainer. These are designated as the cone, which it resembles from its mechanical profile construction; the cup, which fits over the cone and rollers; the rollers, which roll between the cone and cup; and the cage, which retains the rollers properly spaced about the cone. These are all shown in Fig. 15-12.

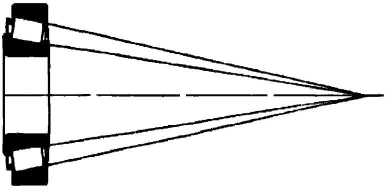

FIG. 15-11. Principle of the tapered roller bearing.

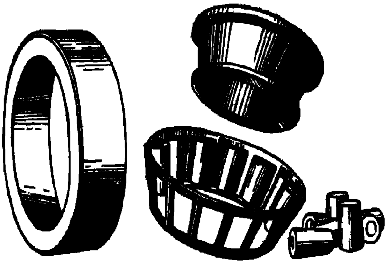

FIG. 15-12. Parts of a tapered bearing: cage, rollers, cone, and cup.

Even in its early stages, this new development in the antifriction bearing field, possessing obvious advantages over other types, met with immediate favor. Manufacturers recognized its merits and soon found occasion to include it in new products, particularly wagons and buggies. That the design is correct is evidenced today by the fact that, although its use has spread to practically every field of industry, it has never been found necessary to depart from the basic principles. Refinements have been made, but the tapered bearing today bears a remarkably close resemblance to the one produced over 50 years ago.

TYPES OF TAPERED BEARINGS

From the foregoing description it will be appreciated that the design of the tapered bearing is such that it is suited particularly well to most positions in machines and will carry all loads regardless of whether they are all radial, all thrust, or in any combination. Even in positions where the load is momentarily changing from one direction to the other, the tapered roller bearing functions perfectly.

There are some locations, however, where certain load or mounting conditions exist which make it desirable to modify somewhat the standard tapered bearing.

These modifications, which do not change the basic principles of the bearing, may be grouped under three natural headings. First, those where the change is made in the raceways or rolling elements, *e.g.*, increasing the angles of the cup, cone, and rollers to obtain greater thrust-carrying capacity; second, by making combinations to secure multiple-row assemblies; finally, bearings developed for certain positions and not suited to general machine applications.

There are occasions also when a designer may wish to adhere to standard dimensions. To meet this condition a light, a medium, and a heavy series of tapered roller bearings have been selected and adopted by the Society of Automotive Engineers as an SAE standard (see Table 15-3).

In the application of the bearings the various factors entering into the operation of the bearing and the machine are considered and the proper tapered bearing is selected. Usually this can be done by using the standard single-row bearing. However, there are occasions when one of the other assemblies is better suited to the design. We are therefore illustrating and describing these various units briefly and indicating the positions where they have found the widest use.

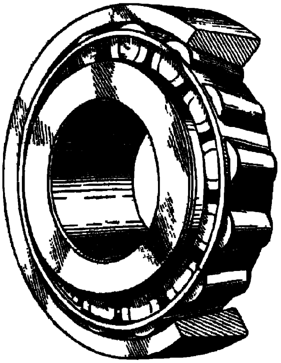

Fig. 15-13. Standard single-row tapered bearing—Type TS.

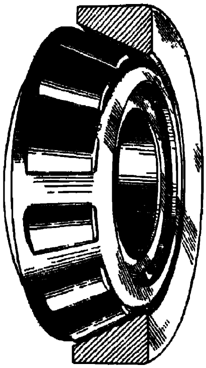

Fig. 15-14. Steep-angle or high-thrust rating bearing—Type TSS.

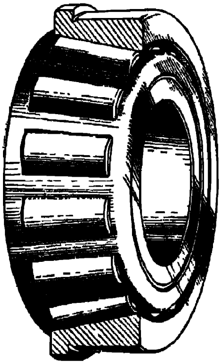

Fig. 15-15. Flanged-cup bearing—Type TSF.

Single-row Bearing—Type ST. In the consideration of the various types of tapered bearings, obviously the standard bearing (Fig. 15-13) is the first to discuss. It is this bearing which is so widely used throughout all industry. The principle of the bearing is understood since the design and construction have been described. It will be recognized, however, that almost endless modifications are possible merely by changing the dimensions or angles of the rolling elements. In actual practice, however, it is essential to make certain basic classifications or "series." These are established by maintaining a fundamental relation between the various components of the bearing. We thus obtain standard or conventional tapered bearings with wide races and long rollers, others with narrow races and short rollers, and a third group representing an approximate mean between the other two. This permits the designer to select the bearing best suited to his needs.

Steep-angle Bearing—Type TSS. In numerous applications, such as power take-offs and worm and bevel-gear shafts, the thrust load predominates, although there is an appreciable radial load. For these positions the high-thrust-capacity or steep-angle bearing has been developed (Fig. 15-14). It differs from the conventional tapered bearing in that the angles of the raceways, as well as the rollers, are quite steep. The fundamental principle of the tapered roller bearing is retained in that lines drawn coincident with the surfaces of the cone, cup, and rollers meet at a common point on the axis of the bearing, thus assuring true rolling motion. The designer therefore obtains all the outstanding advantages of the tapered bearing and in addition a product particularly adapted to heavy thrust loads.

Flanged-cup Bearing—Type TSF. In certain applications, particularly in precision machine-tool spindles, it was found difficult to machine conventional cup seats to a shoulder and maintain the desired accuracy. This was brought about on account of the necessity of removing the housing from the machine after one seat was machined and to set it up in a reverse position to bore the other. Even with the most careful workmanship a variation often occurred so that the cup seats were not in absolute alignment. The required accuracy can now be obtained, however, by boring straight through the housing and facing an outside seat at right angles to the bore. The face thus obtained provides the backing for the flange of the cup (Fig. 15-15).

This bearing is also favored in other machine-tool applications such as gearboxes where there is not sufficient space to use conventional mounting methods. In this case the flange on the cup is set against a face machined on the inside of the gearbox.

In other industrial applications such as sheaves and car wheels, which are frequently cast of manganese steel, it is also used extensively. Manganese steel is exceptionally difficult to machine. In fact, it is necessary to resort to grinding to obtain a finished surface. It would be impractical to attempt to obtain the usual shoulder for cup backing, but here again no difficulty is experienced in grinding a seat on the face of the sheave or wheel hub to locate the flange and thus obtain the required bearing mounting.

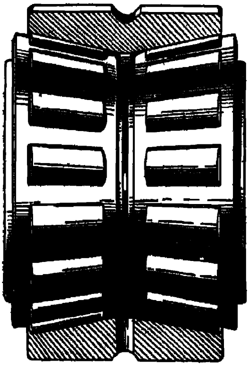

FIG. 15-16. Two-row bearing, double cup, single cones—Type DO.

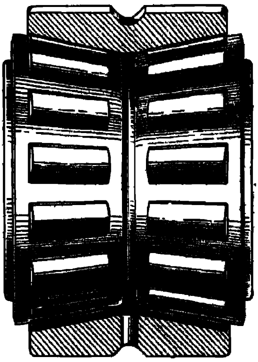

FIG. 15-17. Two-row bearing—Type NA.

The popularity of this bearing has brought about its rapid development so that it is now available in a wide range of sizes.

Multiple-row Bearings. In an ever-widening group of applications, presenting problems not readily solved by the single-row tapered bearing, this type, in one of its many variations, is used extensively. Through the use of these assemblies the designer is able to provide maximum load-carrying capacity in the smallest space, to resist thrust loads from both directions, and to maintain a precise and rigid mounting or a "floating" assembly as desired.

A discussion of multiple-row bearings divides itself naturally into three groups; the two-row cone-adjusted, two-row cup-adjusted, and the four-row cup-adjusted bearings. Within the first two classifications are other types developed to meet specific applications or for certain needs. Thus, in the two-row cone-adjusted assembly will be found the standard two-row cone-adjusted bearing shown in Fig. 15-16 and the "NA" series (Fig. 15-17).

In the two-row cup-adjusted group there has been developed a more extensive range of assemblies. These include the standard two-row cup-adjusted bearing with conventional cone and cups (Fig. 15-19), the tapered-bore bearing, with and without cone puller (Fig. 15-20), and the slotted-cone bearing (Fig. 15-18). At present but one four-row assembly is recommended. That is the four-row cup-adjusted bearing.

Two-row Bearing, Double Cup, Single Cones—Type DO. The two-row bearing, double cup, single cone, employs a double cup with two conventional cones (Fig. 15-16). Two assemblies are possible. Both are identical except that in one case a spacer is introduced between the cones so that the setup or running clearance is established at the time the bearing is assembled. The other, having no cone spacer, requires that the proper setup be obtained by some form of adjusting device. Either form will give satisfactory service. The one having the spacer is usually preferred in those applications where provision must be made for quick removal and replacement of the bearings or where the operating conditions are such that it is unnecessary to provide for take-up after a long period of service.

Numerous applications require that some provision be made to allow for shaft expansion. With this type of bearing it is readily accomplished by securely locking the cones in position and permitting the cup to "float" in the housing. The opposite end of the shaft is usually fixed in position so that the movement is confined to one end.

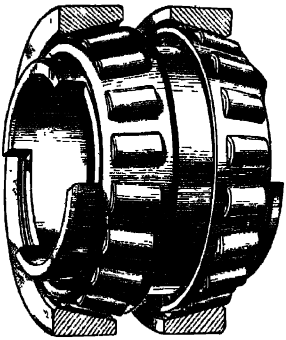

FIG. 15-18. Two-row bearing, slotted double cone—Type DIK.

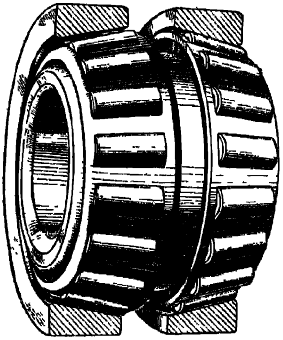

FIG. 15-19. Two-row bearing, double cone, single cups—Type DI.

Two-row Bearing—Type NA. Another construction is shown in Fig. 15-17. Here again we have a double cup and two single cones. In this assembly, however, the cones are butted together so that, when the unit is fixed in place, the proper running clearance is provided. This class is designated as the NA series and is divided into the conventional and steep-angle groups. These bearings, like those already discussed, are suited particularly well to those assemblies where it is not desirable to provide means for take-up in service or where operating conditions require a fixed mounting at one end of an assembly and a certain amount of "float" at the other.

Two-row Bearing, Slotted Double Cone—Type DIK. A bearing developed for use in light-duty pillow blocks is shown in Fig. 15-18. It will be noted that slots are provided in the cone to engage in mating projections on a collar, which in turn is secured to the shaft by means of setscrews. This unit is, of course, not limited to pillow blocks but finds a wide field of usefulness in those applications where cold-finished shafting is used. Since cold-finished shafting may be held to comparatively close limits, it is possible to obtain relatively tight fits on the shaft. This type of bearing, however, is not recommended for heavy-duty service. It should be kept in mind that the bore of these standard bearings is held to the nominal outside diameter of cold-finished shafting. However, tapered-roller-bearing manufacturing practice always provides a plus tolerance, while the standard manufacture tolerance for cold-finished shafting provides for the undersize variation only.

Two-row Bearing, Double Cone, Single Cups—Type DI. The two-row bearing, double cone, single cup, shown in Fig. 15-19, is frequently selected for positions where it is necessary to secure the capacity of a two-row bearing, yet to obtain a simpler mounting than two standard single-row bearings. It is also often used on the fixed end of a shaft when an allowance must be made for shaft expansion. In this case the bearing used on the opposite end is usually one of the double-cup units so set up as to float.

Two-row Bearing, Tapered Bore, Double Cone, Single Cup—Type DIT. The two-row bearing, tapered bore, double cone, single cup, which is identical to the one shown in Fig. 15-19 except that the bore is tapered, was also developed for use on line shafting and in pillow blocks. Like the slotted-cone bearing, however, it is by no means limited to such service but is used extensively in those applications where ease and speed of assembly and disassembly are primary requirements. The usual method of mounting is to use a sleeve tapered to conform to the taper of the bearing. This sleeve should have a saw cut lengthwise to permit it to compress as it advances into the bearing bore, which also provides a rigid seat on the shaft.

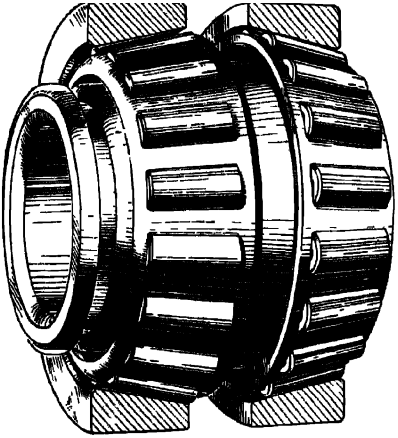

FIG. 15-20. Two-row bearing, tapered bore, double cone with puller—Type DITP.

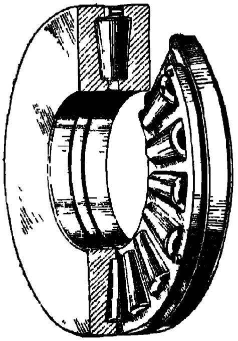

FIG. 15-21. Thrust bearing, heavy duty—Type T.

On line shafting and other positions where it is necessary to be able to slide the complete assembly into position and then fasten it securely, this unit is ideally suited. The field of application is unusually extensive since the tapered sleeve permits a rigid seat on the shaft.

Two-row Bearing, Tapered Bore, Double Cone with Puller—Type DITP. The two-row bearing, tapered bore, double cone with puller, is shown in Fig. 15-20. It differs from the one described above in that a flange is provided on the cone to facilitate removal. The mounting is usually made directly on the shaft. The general field of application covers positions in machines where it is necessary to remove component parts frequently, such as in certain railroad applications and paper-mill machines.

Heavy-duty Bearings. In order to save power, improve performance, and reduce operating costs generally, extensive studies and tests have been made in developing tapered bearings for heavy-duty applications. Numerous installations have been made in various types of rolling mills, cement plants, rubber mills, and other units that develop extreme pressures. Comparative tests have been made, not only to measure the loads which are encountered but likewise to determine the actual savings to be expected. Obviously, this varies with different installations, but in general a saving of from 20 to 50 per cent in power has been obtained.

Power savings, however, are but one of several outstanding advantages since tapered-bearing-equipped rolls may be set to exceptionally close limits, thus accurately maintaining the gauge of the material being rolled. This is frequently an item of major importance, especially in the rubber and metal industries. Likewise the savings in grease and oil are to be considered. In a tapered-bearing installation, carefully designed closures have been developed so that a dual advantage is obtained. First, the lubricant is kept inside the housing so that it performs its primary function of lubricating the moving parts and does not escape to damage the product being handled. Secondly, foreign matter such as water, dust, dirt, or mill scale is excluded.

In addition to the information gained relative to loads and power savings, extensive studies have been made with reference to mountings. This knowledge has been applied as it was acquired so that new applications represent the most advanced thought in tapered-roller-bearing development.

Thrust Bearings—Type T. Although a combination of radial and thrust loads exists much more frequently than either a purely radial or purely thrust load, there are numerous occasions where it is necessary to install a bearing to withstand thrust loads only. To meet this condition, a series of bearings known as the T type is available (Fig. 15-21). These bearings are in regular production in bores ranging from ⅝ in. and a capacity of about 1,000 lb, to massive units having a bore of 11 in. and capable of withstanding over 200,000 lb load.

Special Bearings. Although standard tapered bearings will be found suitable for nearly all applications, at times problems arise requiring special units. The rocker arm of aircraft engines is such an example. The bearing developed for this position is of the two-row double-cup type. In addition to the bearing assembly, *i.e.*, the cone, cup, and rollers, closures are provided so that the unit becomes a complete, self-contained assembly.

MOUNTING TAPERED BEARINGS

In considering the fundamentals of mounting all types of tapered bearings, it must be kept in mind, first of all, that it is impractical to mount a tapered bearing singly. On account of the tapered construction of the bearing, a radial load on one bearing sets up a thrust reaction which must be resisted by the opposed bearing. For this reason tapered bearings must be mounted in pairs. This may be done by using two different types of mountings, referred to usually as direct or indirect, as shown in Fig. 15-22.

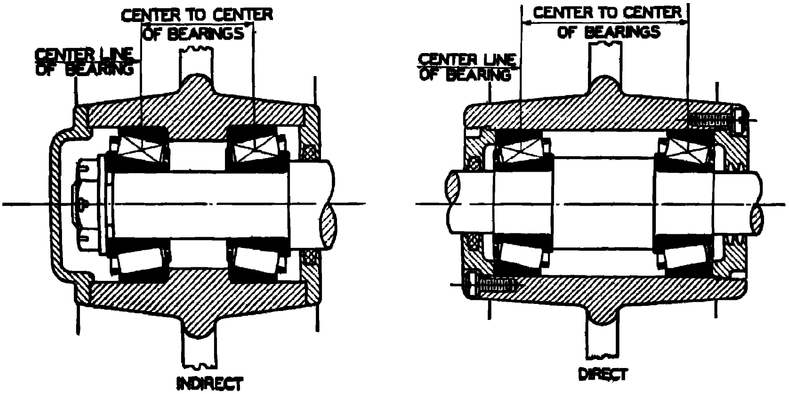

Fig. 15-22. Indirect and direct mounting of tapered roller bearings.

The indirect mounting has the large ends of the rollers of each bearing pointing out or away from the other bearing. The direct mounting has the large ends of the rollers of each bearing pointing toward the mating bearing.

Indirect Mounting. Actual laboratory and field tests have proved the indirect mounting much superior to the direct mounting for wheels, which are usually mounted on a dead shaft. This places the heavy ends of the rollers to the outside, which increases the stability of the application. The distance between bearing centers (Fig. 15-22) should be no less than 15 per cent of wheel outside diameter and preferably 20 per cent.

The indirect mounting is standard in wheels, idler pulleys, sheaves, drums, automotive pinions, and other applications where stability is desired and the distance between bearing centers is relatively short. The increased stability of the indirect over the direct mounting may be better understood by referring to Fig. 15-23. In this illustration the distance between bearing centers *A* is the same. However, the stability of the indirect mounting over the direct is much greater.

Direct Mounting. The direct mounting is used on applications with relatively long bearing centers. It is used on automotive transmission gear shafts differential gear shafts, as well as on machine-tool transmission shafts, general gear reductions, pillow blocks, journal boxes, and other applications that permit wide bearing spreads.

Keeping in mind the two fundamental principles just outlined, each tapered bearing application should be selected to carry the loads to the best advantage. A live shaft application with heavy thrust loads should be designed to carry the thrust on the bearing nearest to the imposed load, *i.e.*, an indirect mounting should be used. Likewise, an overhung bevel-gear arrangement, such as a power take-off, should use a similar mounting since it places the large ends of the rollers adjacent to the heavy radial load. Conversely, where there is a heavy gear or belt-pull load between two bearings, the direct mounting should be used so as to place the large ends of the rollers next to the load.

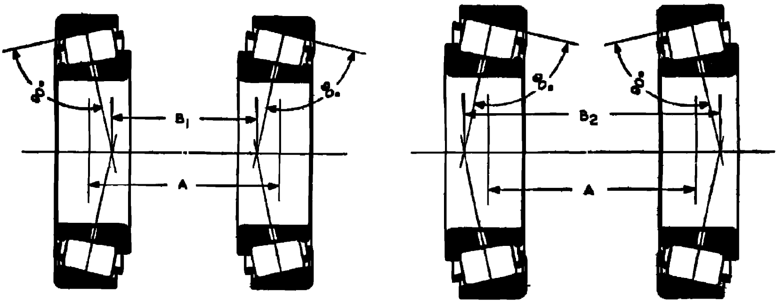

FIG. 15-23. Stability advantage of indirect mounting.

SHAFT AND HOUSING DESIGN

Alternative Methods of Cone Backing—Properly Designed Housing

The setting of the tapered bearing on the shaft and in the housing is important. The usual practice is to seat the cone or cup or both against a shoulder of sufficient height to support whatever thrust and radial loads may be imposed.

Shaft Design. The fillet radius of all shoulder backings should be 1/64 in. less than the radius of the cup or cone.

The conventional method of providing backing is to machine a shoulder on the shaft or in the housing. In some applications it is sometimes necessary to provide alternative backing for the cone by introducing a spacer between the back face of the cone and the shaft shoulder. In this way it may be possible to use a smaller shaft, thereby effecting a production economy.

Another method of providing cone backing for use only with light-duty applications such as conveyor idler rollers or hand trucks is to clamp a split collar tightly to the shaft and lock against end movement by setscrews.

When it is required to maintain maximum shaft strength and also facilitate assembly and disassembly, accurately ground tapered shafts which fit tapered-cone bores are frequently used.

In developing new designs the removal as well as the installation of the bearings should be a matter of primary consideration. The recommended shoulder diameters allow a sufficient portion of the cup and cone to extend so that they may be removed readily. If it is necessary to provide higher shoulders, cored or machined knockout slots should be provided.

Housing Design. In numerous applications it is necessary to provide backing for the small end of the cup with a spacer sleeve supporting the heavy end. This arrangement permits the entire assembly to be clamped firmly in place. When this method is used, some provision must always be made at the small end of the cup for its removal.

Cage clearance must be provided to avoid any rubbing of the rotating bearing cage on the stationary housing parts.

Cylindrical housings and many other applications are chiefly stressed with bending and shearing loads. The designer should consider these loads carefully so that the bearings are not subjected to misalignment, which would bring about early failure.

In split housings, such as generally used with gear reduction units, transmission cases, and similar applications, a cartridge mounting is frequently used, although it is also common practice to mount the bearings directly in the housing. In either case particular attention should be given to the seals so that the lubricant is retained in the housing.

Cleanliness is a matter of the utmost importance, as no bearing will operate successfully in the presence of foreign material, such as core sand, cuttings, scale, or anything of an abrasive nature. When left in the bearing housing, it acts as a lapping agent and leads to rapid wear of the bearings. It is strongly recommended that all inside cast surfaces be cleaned by sand blasting or other means and either painted or coated with a suitable filler to keep the core sand and scale from loosening up in service.

Take-up in Assembly. The take-up feature of the tapered bearing offers many advantages in assembly:

1. Provides wider tolerances for machining bearing seats.
2. Makes possible the adjustment of other dependent parts such as spiral bevel gears and helical gears.
3. Eliminates chatter on machine-tool spindles due to variable bearing clearance.
4. Quieter operation may be obtained by proper bearing adjustment.
5. Elimination of play which may develop after long service.

General applications should have 0.001 to 0.005 in. end play. Special conditions involving elimination of vibration, chatter, unusual quietness, extremely high speed, abnormal heating, or expansion should be taken up with the bearing manufacturer.

The adjustment of the bearing may be made either through the stationary race or the rotating race for speeds up to 1,000 rpm. Above 1,000 rpm, it is usually advisable to make adjustments with the stationary race in order to permit a tight press fit of the rotating race. Adjustment increments of not over 0.003 in. are desired.

In detailing the bearing housing, covers, shaft, etc., provision should be made for machining variations and for future bearing adjustment. When shim adjustment is used, $\frac{3}{32}$ in. should be provided for shims. This will be sufficient for all normal machining variations and in addition will provide a few additional shims for service adjustment. In making assembly, it may be found desirable to place part of the shims at each end of the bearing housing to facilitate adjustment if it becomes necessary. Where threaded adjustment is provided, the $\frac{3}{32}$ in. should be provided for the same reasons. Threads will be used at one end of the assembly only unless it is necessary to vary the position of the entire assembly, in which case threads may be used at each end. Threaded adjusting nuts are used for either cone or cup movement. Light- or medium-duty applications should use nuts with 16 threads per inch and six or more locking castellations. Heavy-duty machinery may require nuts with 12 threads per inch and eight or more castellations. Close-fitting threads are required. Split nuts or housings that can be clamped on mating threads are essential on heavy-duty jobs. Threaded adjustments should not only be positively locked against rotation, but whenever possible the threads should be clamped to ensure tightness against end play.

Whenever possible shim-adjustment devices should be so designed that shims taken out will seat the bearings tighter. This permits field adjustments without requiring new shims. A complete set of shims consists of seven pieces, one of 0.020-in. thickness, three of 0.007-in. thickness each, and three of 0.005-in. thickness each. This permits adjustment increments of 0.001 in. The shims should be smooth sheet metal without rough edges.

Closures—Metal Stampings, Felt, Annular Groove, Stuffing Box, Leather, Cork, Piston Rings, Special, Vertical. In selecting the proper closure design for any tapered-bearing application, it should be kept in mind that the consistency of the lubricant, foreign material to be excluded, speed of the application, and general operating conditions are of unusual importance. Foreign material, such as dust, mill scale, or any hard, gritty substance, will act as a lapping agent and quickly destroy the bearing. Likewise, water, acid, or inferior lubricant will etch the highly finished surfaces and also bring about early failure. A variety of closure designs is therefore available to assist engineers in obtaining the most satisfactory application.

Cone- and Cup-fitting Practice. The adjustable feature of a tapered bearing is an important advantage since it permits the heavy press fits required in numerous applications. Regardless of the fit, the tapered bearing may be set to the correct running clearance after all the other parts have been assembled in position. The proper adjustment of the bearing is therefore independent of variations in mounting conditions.

However, careful study should always be given to the selection of the proper fitting practices, and Tables 15-8 and 15-9 cover in some detail recommendations which should be followed in industrial installations.

Turned Shafts. It is recommended that all cone seats be ground. In those cases where this is impossible a minimum cone seat should be provided equal to the nominal cone bore plus 0.0005 in. per in. of cone bore, to which should be added 0.001 in. for maximum cone seat diameter.

This applies to transmissions, speed reducers, electrical machinery, and all low-speed, heavy-duty, continuous-service applications or applications subject to shock, and using cones with a bore of over 2.5000 in. For all other applications use the fitting practice provided for ground shafts. It is always best to refer any new designs directly to the bearing manufacturer for attention and mounting suggestions.

While there are certain basic rules which should be followed in mounting tapered bearings, some variation is permitted where necessary to meet special conditions of mounting, assembly, and different types of service. For example, on a stationary spindle, a loose fit of the bearing cone can be permitted in some applications to facilitate assembly and disassembly. Such a condition is found in the front wheels of automobiles. In this application, since the spindle itself is usually made of a high-grade alloy steel, there is very little likelihood of damage to either the spindle or the bearings owing to the cone creeping on the spindle. Furthermore, the speed is not high. In applications such as this, however, it is essential to make the outer races or cups a tight press fit in the hub.

When cones are mounted on rotating shafts, especially where the loads are heavy or the speeds high, it is essential that the cones be a tight press fit. Some deviation from this rule may be permitted in exceptional cases, but only where all conditions surrounding the bearing and its operation are known. In mountings where the bearing adjustment is made through the cone, it is possible to fit the cone on the shaft with a light press or even a slip fit provided that the shaft is hard and the parts immediately back of the cone are hard. It should be understood, however, that the ideal mounting is a tight press fit. In many bearing applications incorporating a rotating shaft, adjustment is made through the bearing cup in which case the cone can be a tight press fit and the cup a relatively loose fit in the housing. There should be no tendency for the cup to rotate in the housing under these conditions.

Stationary-shaft Applications. It is possible and quite often desirable to mount cones loosely on stationary-shaft applications where the average speed is not likely to exceed 500 rpm. This permits the cone to creep, thereby utilizing the full working surface. It also facilitates assembly. Examples of such applications are automobile front wheels, tractor front wheels, farm-implement wheels, shop-truck wheels, and similar applications. It is, of course, necessary to provide against excessive looseness

of the cones even in these applications, and cone seats and shoulders backing up the cones should be smoothly machined or ground. The actual fit in this type of application where alloy-steel or other high-grade heat-treated steel spindles are used will vary from 0.0002 loose to 0.0012 in. loose in the small-size bearings, and in the larger sizes the fits will vary from 0.0002 loose to 0.0017 in. loose. Where ordinary carbon-steel spindles are used, a fit of 0.0005 tight to 0.0015 in. loose is recommended.

Light press fits of cones are recommended for stationary-shaft applications such as found on loose pulleys, idler gears, and similar applications. In such applications, where speeds may run from 500 to 1,000 rpm, loose-fitting cones should be avoided if possible. Assembly problems may necessitate a loosely fitted cone, but in these cases care should be taken to see that a good steel is used in the shaft and parts adjacent to the bearing. On small bearings these fits will vary from 0.0005 tight to 0.0005 in. loose and on the larger bearings from 0.001 tight to 0.001 in. loose, the desired fit being about a line-to-line condition.

In applications where speeds are above 1,000 rpm or where the loading condition is particularly severe, tight fits are recommended. The tightness of the cone fit should be approximately 0.0005 in. press per in. of shaft diameter. If adjustment is to be made through the tightly fitted cones, it will be necessary to heat the cones during assembly and make the proper setup while the cones are still hot. Where precision bearings are used in which cone bores are held to 0.0005-in. tolerance, a lighter fit may be necessary to maintain utmost precision. In such cases the shaft must be ground, and a press fit of from 0.0005 in. tight to 0.0015 in. tight is satisfactory.

Tight press fits are required on cups in stationary-shaft applications in practically all cases. A loose cup in a rotating housing such as a wheel hub is bound to rotate with respect to the housing itself, and trouble is very likely to be encountered. In some cases where the adjustment is made through the cup, such a fitting practice may be necessary. Before adopting such a design, it is recommended that the bearing manufacturer be consulted so that proper recommendations can be made.

Cups up to 3 in. in outside diameter should be mounted with a press fit of from 0.0005 in. tight to 0.0025 in. tight; above 3 in. in outside diameter, the fit recommended is from 0.001 in. tight to 0.003 in. tight. Where precision bearings are supplied with outside-diameter tolerance of +0.0005 in., a press fit of from 0.0005 in. tight to 0.0015 in. tight is satisfactory up to 5 in. outside diameter, and above that the recommended fit is from 0.0005 in. tight to 0.002 in. tight.

Rotating-shaft Applications. On rotating-shaft applications the cone fit on the shaft is very important. This is particularly true where the speeds are high and loads severe. Where the loads encountered are heavy, it is absolutely essential to have the cones a tight press fit regardless of whether the adjustment is made through the cone or through the cup. In a very few special applications where the loads are relatively low, cones are fitted loosely on the shaft, but in these cases special provision is made to ensure against excessive turning and wearing of the shaft itself. In general, all cones supplied with a standard bore tolerance of +0.001 in. should be fitted with a normal press fit of 0.0005 in. per in. of shaft diameter. With cones that are supplied with a cone-bore tolerance of +0.0005 in. and used in precision mountings such as machine-tool spindles or where the cones are mounted on hardened and ground shafts, a press fit of from 0.0005 in. tight to 0.0015 in. tight is satisfactory.

Where bearing adjustment must be made through the cone and where the loads are light, a looser fit is sometimes used. Such a loose fit can be used satisfactorily only on a hardened shaft and with the shoulder immediately back of the cone also hardened. An example of such an application is the forward pinion bearing used in passenger-car and truck axles. The cone fit used in these applications is from 0.0005 tight to 0.0005 in. loose. Wherever possible, a further safeguard against excessive rotation should be provided by clamping the cone endwise. This construction is quite common where shims are used for initial setup.

In rotating-shaft applications the bearing cups are, of course, stationary, and an adjustable fit is in most cases satisfactory. Cups provided with the standard tolerance of +0.001 in. on the outside diameter up to 5 in. should be fitted from 0.001 in. loose to 0.001 in. tight. Above 5 in. outside diameter, these cups should be fitted from

0.002 in. loose to 0.001 in. tight. Adjustable cups up to 5 in. outside diameter, which are supplied with a tolerance on the outside diameter of +0.0005 in., such as are used in machine-tool and other precision applications, should have a fit of 0.0005 in. loose to 0.0005 in. tight. Cups above 5 in. outside diameter and supplied with the same tolerance should be mounted with a fit from 0.001 in. loose to 0.0005 in. tight.

Where adjustment is made through the bearing cone, the cup should be given a tight press fit in the housing. Cups up to 3 in. outside diameter and furnished with the standard tolerance of +0.001 in. used in a mounting with cone adjustment should be given a press fit of from 0.0005 in. tight to 0.0025 in. tight. All cups above 3 in. outside diameter should be fitted from 0.001 in. tight to 0.003 in. tight. Cups up to 5 in. outside diameter and furnished with an outside-diameter tolerance of +0.0005 in. should be given a press fit of from 0.0005 in. tight to 0.0015 in. tight. Cups with the same tolerance but over 5 in. outside diameter should be fitted from 0.0005 in. tight to 0.002 in. tight.

Where double bearing mountings are used, the bearing cups at one end of the mounting are usually allowed to float in the housing to provide for expansion or machining variations. In these mountings, adjustments are made through the cones, and the cups are mounted back to back either directly against each other or through a spacer. Standard cups with outside-diameter tolerance of 0.001 in. are fitted from 0.000 in. loose to 0.002 in. loose up to 5 in. outside diameter; from 0.001 in. to 0 003 in. loose from 5 in. outside diameter up to 7.500 in. outside diameter; and 0.002 in. to 0.004 in. loose over 7.500 in. outside diameter. In precision bearings up to 5 in. outside diameter, the cups are fitted in the housing from 0.000 in. loose to 0.001 in. loose; above 5 in. outside diameter the fit is 0.000 in. loose to 0.0015 in. loose. All precision-bearing cups have an outside-diameter tolerance of +0.0005 in.

The foregoing information relative to fitting practices to be followed on tapered cups and cones is, of course, general and should serve as a satisfactory guide in the majority of standard bearing applications. In order to facilitate the specifications of proper shaft diameters and housing bores, Tables 15-8 and 15-9 have been prepared. Certain types of applications and mountings have been classified so that the selection of the proper fit is comparatively simple.

In the "NA" series bearing, certain fits must be observed in order to obtain the proper running clearance, which is established at the time of manufacture. These fits should be obtained from the bearing manufacturer.

As stated previously there are numerous special bearing applications for which special fitting practices are required. Fitting practices for such applications should be obtained directly from the bearing manufacturer.

SELF-ALIGNING ROLLER BEARINGS

BY BRYCE RULEY

Senior Engineer, SKF Industries, Inc.

This subsection describes those types of roller bearings which are inherently self-aligning, *i.e.*, able to adjust to misalignment between shaft and housing bore without loss in carrying capacity.

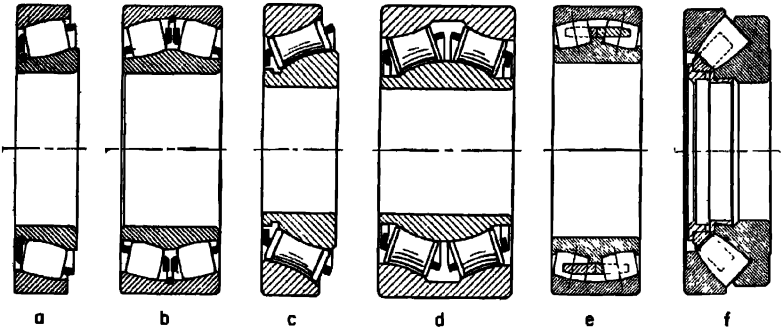

FIG. 15-24. Self-aligning roller-bearing types: (*a*, *b*) spherangular; (*c*, *d*) concavex; (*e*) spherical; (*f*) spherical thrust.

The ability to self-align is obtained by making either the inner or the outer race of the bearing a section of a sphere. The other ring and the roller assembly can align freely on this surface to adjust to any initial or operating misalignment.

Various designs which give approximate line contact between rollers and raceways and allow self-aligning between inner and outer rings are shown in Fig. 15-24 and described in detail in the material that follows.

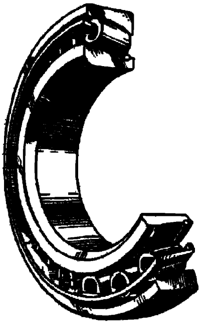

FIG. 15-25. Spherangular roller bearing.

SPHERANGULAR BEARING

The spherangular bearing is a symmetrical barrel roller type of angular-contact bearing designed for combined radial and thrust loads. The bearing is self-aligning, but the roller and ring curvatures are such that proper load distribution is obtained even under conditions of misalignment. The load direction is always through the largest diameter of the roller.

The single-row bearing is made with a separable outer ring, while the double row is nonseparable. In the larger sizes the double row is made with a center flange for roller guidance.

The thrust capacity depends on the angularity of the rollers, *i.e.*, the angle at which the rollers are placed with respect to the radial plane of the bearing. This angle varies from approximately 10 to approximately 25 deg, the higher angles being used where higher thrust capacity is required (see Fig. 15-25).

CONCAVEX ROLLER BEARING

The concavex roller bearing is an angular-contact roller bearing designed to carry combined radial and thrust loads. The rollers are curved so that the largest diameter is at the ends of the rollers, *i.e.*, the rollers are concave in one direction and convex in the other. These rollers conform to the spherical inner race to give line contact and self-alignment without reduction in carrying capacity.

The single-row bearing has a separable outer ring. The double-row bearing is sometimes made with two separable outer rings and sometimes with only one non-separable outer ring.

The single-row bearing can carry thrust or combined loads in one direction only, while the double-row bearing can carry reversed thrust or a pure radial load. A number of bearing series are available in this bearing type to handle a wide variety of load conditions.

SPHERICAL ROLLER BEARING

The spherical roller bearing is a double-row type designed to carry heavy radial, thrust, or combined loads. Since the two rows of rollers have opposed angles of contact, the bearings can support reversed thrust loads or combined loads in any direction. The outer race of the bearing is a section of a sphere in which the roller assembly and inner race move to adjust to any misalignment.

The rollers are usually made with a tapered barrel shape. This allows a close approach to true rolling motion between rollers and raceways and holds the ends of the rollers firmly against the central guiding flange assuring proper roller guidance.

This bearing is manufactured in a wide variety of dimensions and dimensional proportions so that a bearing selection can be made to suit any load condition. This bearing is available with either a straight bore or a tapered bore to suit a variety of mounting conditions (see Fig. 15-26).

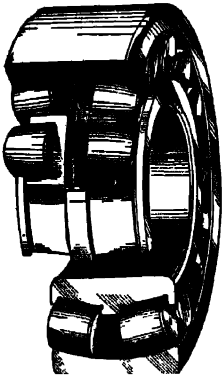

FIG. 15-26. Spherical roller bearing.

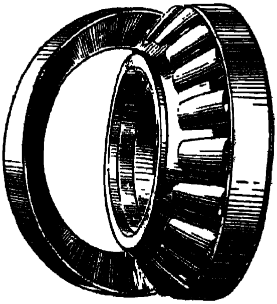

FIG. 15-27. Spherical roller thrust bearing.

SPHERICAL ROLLER THRUST BEARING

The spherical roller thrust bearing is a single-row angular-contact bearing designed to carry heavy thrust loads or combined loads that are predominantly thrust. The outer race is a spherical section making the bearing self-aligning.

The rollers have a tapered barrel shape which holds the roller ends against the high guide flange on the inner ring, assuring proper roller guidance.

The lubrication preferred for this bearing is an oil of fairly high viscosity. The bearing is designed so that the oil is pumped outward from the bearing center over the rollers, cage, and guide flange, giving uniform lubrication to all bearing parts.

Spherical roller thrust bearings may be mounted in pairs, back to back, or face to face, to carry heavy reversed thrust loads (see Fig. 15-27).

BALL BEARINGS

BY BRYCE RULEY

Senior Engineer, SKF Industries, Inc.

Ball bearings fall into a few main classes, each class having different characteristics. Figure 15-28 shows some common ball-bearing types and the following paragraphs describe these types more fully.

SINGLE-ROW RADIAL BALL BEARINGS

The *deep-groove* or *Conrad* type of radial ball bearing has raceways which consist of deep continuous grooves cut in the bearing rings. Since the radii of the grooves are only slightly greater than the radii of the balls, the balls conform closely to the raceways, giving good support to the areas of contact and accurately guiding the direction of rolling of the balls.

Deep-groove ball bearings can carry radial, thrust, or combined load. The wide range of load and operating conditions for which deep-groove ball bearings give excellent service make this bearing a popular general-purpose bearing for light and medium loads.

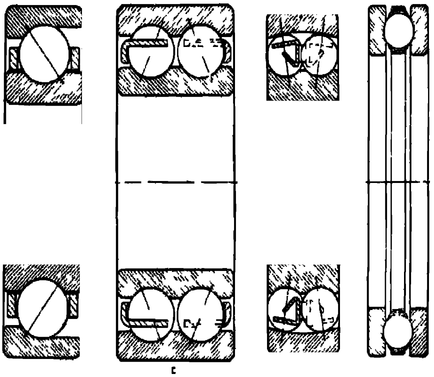

FIG. 15-28. Ball bearings. Deep-groove radial—*a*; angular-contact—*b*; double-row—*c*; self-aligning—*d*, ball thrust —*e*.

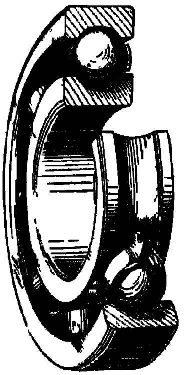

FIG. 15-29. Deep-groove ball bearing.

A variation of the deep-groove bearing is the *maximum* or *filling-notch* type. This bearing has raceways which are grooves cut in the bearing rings, but notches have been cut in the groove shoulders on one side of the bearing to allow a greater number of balls to be inserted in the bearing (see Fig. 15-29)

The maximum-type bearing is designed to carry radial loads and combined loads that are predominantly radial. It can carry moderate thrust loads but is not usually recommended for these.

Radial ball bearings are made in a *separable* type in which one shoulder of the outer race has been cut down to allow a full-complement ball assembly to be snapped in over the low shoulder. This bearing can carry radial load and thrust or combined load in one axial direction only. This type of bearing is sometimes called a *magneto*-type bearing.

A number of other modifications have been made to the basic radial ball bearing. In current manufacture are bearings with extended inner races, bearings with snap rings, tapered-bore bearings, bearings with built-in plates or friction seals, etc.

ANGULAR-CONTACT BALL BEARING

If a deep-groove bearing with considerable internal clearance or slackness is loaded by a thrust load, the bearing moves so that the load passes through the balls at an angle to the radial plane of the bearing. This angle is called a contact angle. Radial ball bearings have an initial contact angle of 0 and may under heavy thrust load have a contact angle of 15 deg or more.

Some bearings are made so that they have an initial contact angle. This improves their thrust-carrying ability but prevents them from carrying pure radial load unless they are opposed by a similar bearing. Bearings of this type are called *angular-contact* bearings. In current production are bearings whose initial contact angles range from 15 to 40 deg. These bearings are designed to carry light or medium combined loads which are mostly thrust and are often used to carry thrust loads at high speeds (see Fig. 15-30).

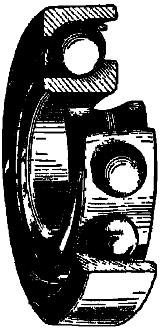

Fig. 15-30. Angular-contact ball bearing.

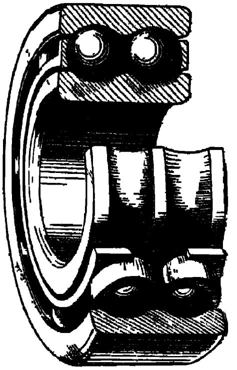

Fig. 15-31. Double-row ball bearing.

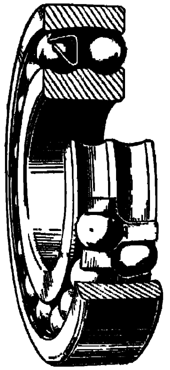

Fig. 15-32. Self-aligning ball bearing.

DOUBLE-ROW BALL BEARINGS

Double-row ball bearings are similar to two single-row radial bearings placed side by side except that the raceways for both rows are set in common rings. This bearing is sometimes made as a deep-groove type, sometimes as a maximum type, and sometimes as a double-row angular-contact bearing with opposed contact angles.

Double-row bearings have nearly twice as much radial capacity as single-row bearings, but their thrust capacity is usually about the same as the single-row bearing. This bearing is more sensitive to misalignment than the single row since a slight misalignment can result in one row of balls carrying all the load (see Fig. 15-31).

SELF-ALIGNING BALL BEARINGS

The *self-aligning* ball bearing is a double-row type in which the grooved outer races have been replaced by a single spherical-section raceway. This bearing is thus able to self-align to adjust for any misalignment between shaft and bearing-housing bore.

Self-aligning ball bearings usually have slightly less radial capacity and substantially less thrust capacity than the equivalent size of deep-groove ball bearing. However, their ability to adjust to misalignment gives them more effective capacity under conditions where considerable misalignment is present.

These bearings are made in a number of series so that the customer has some latitude in selecting bearings to match his needs (see Fig. 15-32).

BALL THRUST BEARINGS

Ball thrust bearings are grooved-type bearings with contact angles of 90 deg. This means that the grooves are cut in rings so that the load line passes through the balls in direction parallel to the shaft.

Ball bearings can carry pure thrust loads only. If radial loads occur, they must be carried by separate bearings. Ball thrust bearings run under considerable difficulty at high speeds since centrifugal and gyroscopic forces act on the balls to prevent true rolling motion. This increases the friction in the bearings and gives them a low limiting speed.

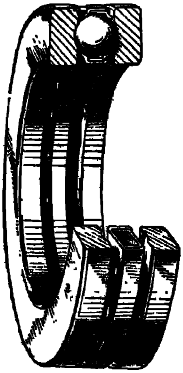

FIG. 15-33. Ball thrust bearing.

Ball thrust bearings are very sensitive to misalignment. Some bearings are made with self-aligning seats on one bearing ring. This proves fairly satisfactory in caring for initial misalignment but has not been nearly so successful with misalignment that varies with operating conditions.

Two-directional ball thrust bearings have been made to carry reversed thrust loads (see Fig. 15-33).

ELECTRICAL SPEED CONTROL

BY R. B. IMMEL

Design Engineer, Industrial Control Engineering Department,
Westinghouse Electric Corporation, Buffalo, N. Y.

INTRODUCTION

The successful operation of many motor-driven machines or devices depends upon the speed control. Some machines require operation over a wide range of speed, while others require operation at a closely regulated speed. The speed-control means may be mechanical, completely electrical, or a combination of mechanical and electrical means. However, electrical speed control is generally characterized by the ease with which relatively small changes in voltage and current can effect changes of very large magnitude in the power circuits and the motor output speed, torque, or horsepower characteristics. In general, electrical speed-control means are more flexible, quicker and easier to adjust, faster in response, and much more suitable for complicated sequence operations and interlocking than any of the other speed-control methods.

Electrical speed control can be accomplished by manual or automatic control devices. It is particularly well adapted to automatic speed control, and this type of control should be used where it is economical to do so. Compared to many mechanical speed-control mechanisms, the electrical control system may also provide a much wider range in speed control.

The selection of the proper control equipment for a specific application is equally as important as the selection of the most suitable motor. A great many factors, such as the type of power supply available, the type of machinery to be driven, the speed range desired, the type of control wanted, the location of the electrical equipment, the duty cycle, the operating personnel available, the cost, etc., must be taken into consideration in selecting the most suitable electrical apparatus for the application.

The type of power supply available is usually given the first consideration in the selection of an electrical drive which consists of the motor, control, and auxiliary control apparatus. However, in many applications the speed-control factor is predominant over the power supply in selecting the drive that will in the long run be the most economical and satisfactory.

A complete knowledge of the essential features of the driven machinery and the load characteristics is required before an intelligent selection of the electrical drive can be made. With the exception of the a-c synchronous-motor drives and drives with speed-regulating controls, *the speed of many electrical drives is determined directly by the torque requirements of the load.* When the speed-torque requirements of a driven load are definitely known, the electrical drive performance can be predicted reasonably accurately.

The relationship between the drive torque, the horsepower output, and the speed can be expressed by the following equation:

$$T = (\text{hp} \times K)/N \qquad \text{or} \qquad \text{Hp} = (T \times N)/K$$

where T = torque
hp = horsepower
N = speed
K = conversion constant

When the torque T is expressed in pound-feet, and the speed N in rpm, the constant K is equal to 5,250.

ELECTRICAL DRIVE CLASSIFICATION

Electrical drives may be classified by the load requirements which are generally known as constant torque, constant horsepower, a combination of constant torque and constant horsepower, and variable torque.

Constant-torque Electrical Drives. Compressors, chain-grate stokers, belt conveyors, cranes or hoists, plunger pumps, and loading machines are generally considered to be constant-torque loads. Figure 16-1 illustrates the speed, torque, and horsepower relationships of a constant-torque electrical drive. With a constant-torque load, the total pull at any time will be constant and independent of the load. Speed adjustment is required to vary the amount of material being transported, and the horsepower required will be a direct function of the speed. Friction also represents a constant-torque load, and in some inefficient machines, this friction load may be predominant and cause the machine to have a constant-torque characteristic regardless of the useful-load characteristics.

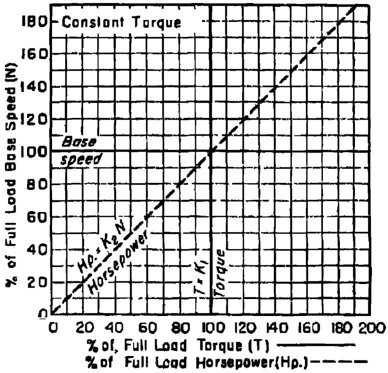

Fig. 16-1. Characteristics of a constant-torque electrical drive.

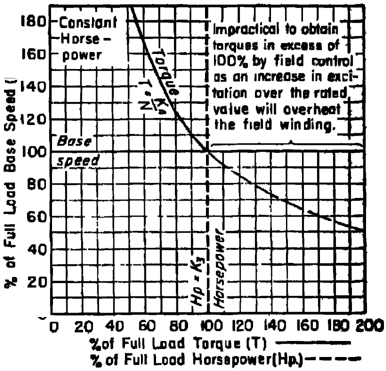

Fig. 16-2. Characteristics of a constant-horsepower electrical drive.

Constant-horsepower Electrical Drives. Figure 16-2 shows the relationship between the speed, horsepower, and torque for constant-horsepower electrical drives. Machine tools, lathes, planers, drill presses, and any machine with a controlled load is usually considered to be a constant-horsepower load. When the load (or torque) is light, the machine can be operated at a relatively fast speed; and when the load is heavy, the machine should be operated at a slower rate of speed. For example, consider the load characteristics of a lathe. As the cutting speed is increased, the depth of cut is decreased to reduce the torque required to drive the load. Since the horsepower is proportional to the product of the torque and speed, the horsepower required for this type of application is approximately constant at any speed. This is not unexpected as the volume of metal that can be removed per unit time is approximately constant over the entire speed range.

For a core-type paper-winding machine, as the diameter of the roll increases, the speed of the driving motor must be decreased to hold the sheet tension and linear paper speed constant. Constant tension at constant linear paper speeds requires constant horsepower over the complete range regardless of how the motor speed varies with the diameter of the roll.

Constant-torque—Constant-horsepower Electrical Drives. For loads requiring a wide speed range, a combination constant-torque and constant-horsepower drive is often utilized. The characteristics of this type of drive are shown by Fig. 16-3. This type of drive has been used very successfully for elevator and metal-working planers. This drive characteristic is typical of a d-c shunt motor which has armature-voltage control below the base speed for constant torque and field control above the base speed for constant-horsepower output.

Variable-torque Electrical Drives. Fans, blowers, and centrifugal pumps are considered to be variable-torque loads as the torque varies directly with the speed. The horsepower is usually considered to vary approximately as the square of the speed for a variable-torque load. The characteristics of a variable-torque load are illustrated in Fig. 16-4.

In Figs. 16-1 to 16-4 subscripts have been added to the constant K to indicate that the numerical value of K is not the same.

It should be thoroughly understood that the characteristics indicated by Figs. 16-1 to 16-4 are the maximum or boundary conditions for the torque or horsepower that the electrical drive motor can safely deliver. It is not likely that a single load will have exactly the same speed–torque characteristics as the drive motor and control; but the load-speed–torque requirements must never exceed those of the drive motor.

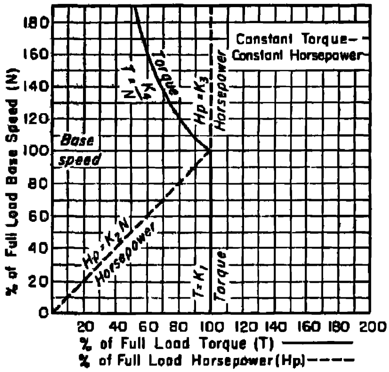

FIG. 16-3. Characteristics of a constant-torque–constant-horsepower electrical drive.

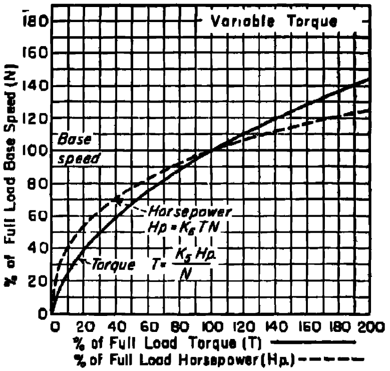

FIG. 16-4. Characteristics of a variable-torque electrical drive.

As the drive-motor torque and horsepower output are directly related to the current that the motor draws from the line, the maximum torque or horsepower limitations must not be exceeded, or the motor temperature will exceed its rated and safe temperature rise. As a motor generally has considerable thermal capacity, intermittent overloads are not objectionable for some applications like cranes, hoists, etc., where intermittently rated motors are usually used to obtain the most economical installation.

The drive motor and control for a given load must always be selected to satisfy the load requirements under all conditions of speed and torque. Obviously, the motor torque available at each speed must be equal to or greater than the requirements of the driven load. The maximum torque and speed requirements of a load usually determine the horsepower rating of the drive, and this rating may be many times that required when the machine is operated at other than maximum speed.

With the exception of a-c synchronous-motor drives and drives where the motors are operated in conjunction with automatic speed-regulating controls, the speed will be determined directly by the driven load. The motor will always operate at a speed where its speed–torque characteristics are exactly in equilibrium with the speed–torque requirements of the driven load. This condition is illustrated later in this section on some of the curves where the operating speeds are predicted graphically by plotting the load and drive-motor characteristics on the same set of coordinates.

Every electric drive motor possesses certain inherent speed characteristics by which it can be classified into a specific category. The following classifications have been adopted by the National Electrical Manufacturers Association (NEMA) and should help to suggest the type of motor to be applied to a specific application.

A *constant-speed* motor is one the speed of normal operation of which is constant or practically constant. For example, a synchronous motor, an induction motor with small slip, or an ordinary direct-current shunt-wound motor.

A *varying-speed* motor is one the speed of which varies with the load, ordinarily decreasing when the load increases; such as a series motor, or an induction motor with large slip.

An *adjustable-speed* motor is one the speed of which can be varied gradually over a considerable range, but when once adjusted remains practically unaffected by the load; such as a shunt motor with field-resistance control designed for a considerable range of speed adjustment.

An *adjustable varying-speed* motor is one the speed of which can be adjusted gradually, but when once adjusted for a given load will vary in considerable degree with change in load; such as a compound-wound direct-current motor adjusted by field control or a slip-ring induction motor with rheostatic speed control.

A *multispeed* motor is one which can be operated at any one of two or more definite speeds, each being practically independent of the load. For example, a direct-current motor with two armature windings, or an induction motor with windings capable of various pole groupings.

The basic methods of speed control for d-c and a-c motor drives have been illustrated with particular emphasis on the speed control. While this section is not directly concerned with methods of starting motors, speed control and starting are inherently linked together, and the starting means must also be considered. The apparatus shown in the illustrations may be manually or magnetically operated to illustrate the diversity of the choice of equipment. Manual speed-control apparatus is generally simpler and less expensive than magnetically operated control equipment. For automatic operation, overload protection, interlocking, and limit or auxiliary switch control, manual control is not generally satisfactory. The use of magnetically operated control is imperative to obtain this type of operation.

Emphasis has been placed in particular on the speed range, speed regulation, size of the drives available, and the economics of one speed-control system over another.

It should be borne in mind that there are many variations of the basic speed-control schemes shown; however, a thorough understanding of the basic motor characteristics and the methods that can be utilized to control the speed of a motor will make it possible to understand many of the more complicated control schemes. Some times artificial loads are imposed on the driving motor to provide more stable operation. These control systems are considered to be too special for this section and will not be discussed.

D-C MOTOR DRIVES—D-C POWER SOURCE

Although a-c induction motors are the most widely used type of motor because of their relatively low cost, simplicity, and the extensive distribution of a-c power, there are many applications where the use of d-c drive motors is absolutely necessary to meet satisfactorily the operating requirements. In general, an adjustable and wide speed range with a very accurate means of speed control can be obtained only with d-c drives.

D-c Shunt-wound Motor Drives. Shunt-wound d-c motors are essentially constant-speed motors with the field winding connected in parallel with the motor armature. When operated on a constant voltage supply and with a fixed value of field current, they operate at essentially constant speed regardless of variations in the load. There is some change in speed or regulation as the load varies from no load to full load, but in general, at the base speed this does not exceed 12 per cent for integral-horsepower motors up to 5 hp and 10 per cent for motors larger than 5 hp.

Constant-speed motors are usually suitable for a speed range up to 2:1 by field control and for constant-horsepower output, provided the top speed does not exceed the maximum safe rpm for which the motor was designed.

Direct-current motors which have a speed range by field control of 3:1 or more are considered to be adjustable-speed motors. Standard motors are available for 3:1

and 4:1 speed ranges. Motors with speed ranges up to 8:1 are available, but these motors are more expensive as special designs and field windings must be used.

D-c-motor Basic Characteristics and Speed Formulas. The direction of the motor rotation which results from the relationship between the direction of the current flow in the armature and the direction of the magnetic lines of force produced by the shunt field for motor operation is such that a counter emf E_A is generated in the armature conductors as they pass through the magnetic field. This counter emf varies from zero at armature standstill to approximately line voltage less the armature-circuit voltage drop I_AR_A at full speed. This counter emf E_A is almost directly proportional to the motor speed.

This characteristic can be represented by the following equation:

$$E_A = K\Phi N$$

where E_A = counter emf
K = motor constant
Φ = field flux
N = speed

Figure 16-5 shows this inherent motor characteristic graphically. The counter emf is in opposition to the impressed line voltage V. Hence, the net voltage that causes current to flow in the armature conductors and which produces motor action is the difference between the impressed line voltage V and the counter emf E_A.

This relationship can be expressed by the following formulas:

$$I_A = (V - E_A)/R_A \qquad \text{or} \qquad V = E_A + I_AR_A$$

where I_A = armature current
V = line voltage
E_A = counter emf
R_A = total armature circuit resistance

The basic d-c-motor speed equation can now be derived as follows:

as $$V = E_A + I_AR_A$$
and $$E_A = K\Phi N$$
then $$N = (V - I_AR_A)/K\Phi$$

where N = speed
V = line voltage
I_A = armature current
R_A = total armature circuit resistance
K = motor constant
Φ = field flux

As the product of the full-load armature current I_A and the armature resistance R_A can be considered a constant, an examination of the preceding speed equation shows that the motor speed can be varied by changing the line voltage V when the shunt-field flux Φ is held constant. This equation also shows that a properly designed motor should have an I_AR_A voltage drop which is small in comparison to the impressed line voltage V so that the speed will not vary appreciably with changes in the armature current I_A. In general, this value is approximately 10 per cent of the line-voltage value V for shunt motors.

For constant shunt-field excitation, the change in speed with a change in the per cent of line voltage V impressed on the armature of a shunt motor is shown by Fig. 16-6.

The motor speed can also be changed by varying the shunt-field flux Φ. If the impressed line voltage V is held constant, the speed will increase with a decrease in the flux Φ. This characteristic is shown by Fig. 16-7.

Because of the physical limitations, the shunt-field flux cannot readily be increased beyond the value that is produced when the field is energized at rated line voltage V for the slowest speed. As previously shown by Fig. 16-6, to obtain speeds below the base or full-field speed, the voltage applied to the armature must be reduced.

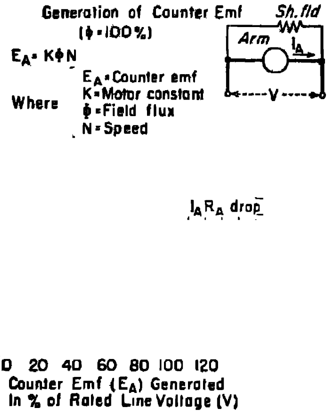

Fig. 16-5. Speed-counter emf curve for a typical d-c shunt motor.

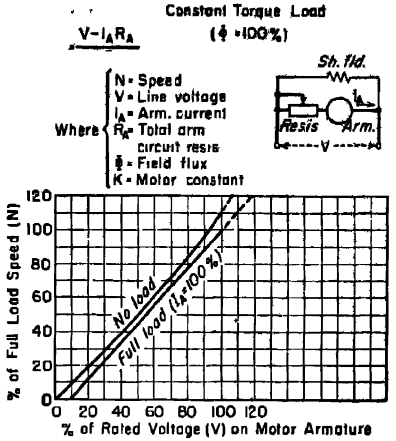

Fig. 16-6. Speed–per cent impressed armature-voltage curve for a typical d-c shunt motor.

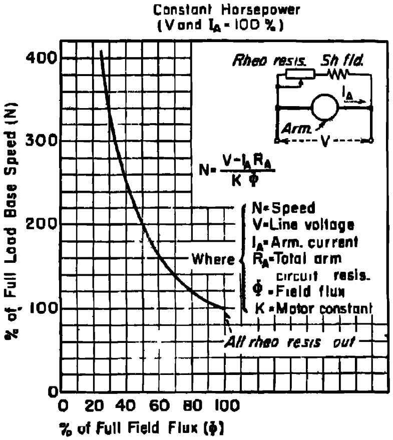

Fig. 16-7 Speed–field-flux curve of a typical d-c shunt motor.

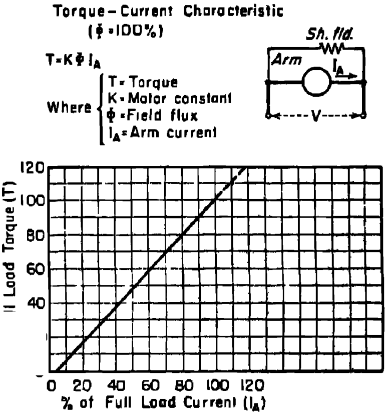

Fig. 16-8. Torque-armature-current characteristic of a typical d-c shunt motor.

D-c-motor Basic Torque Characteristic and Formula. The torque developed by a d-c shunt motor is proportional to the product of the field flux Φ and armature current I_A. The torque can be expressed by the following equation:

$$T = K\Phi I_A$$

where T = torque
K = motor constant
Φ = field flux
I_A = armature current

Most controllers are arranged so that the motor shunt field is fully excited during the starting and accelerating period. This helps the motor to develop the required torque without excessive armature current. A typical torque and armature-current curve is shown by Fig. 16-8. For constant field excitation, the torque is almost directly proportional to the armature current. The motor torque can be controlled by varying the applied armature voltage or by limiting the armature current by means of a series resistor.

Speed Adjustment by Armature-resistance Control.

Speed Range:
2:1 (50 per cent speed reduction by armature-resistance control)
Speed Decrease from No Load to Full Load:
Approximately 50 per cent at low speed
Approximately 10 per cent at base speed
Horsepower:
¼ to 50

Figure 16-9 shows the apparatus required for the simplest and least expensive d-c adjustable-speed drive. This type of controller is manually operated and provides a means for varying the resistance in the armature circuit and the voltage applied to the motor armature.

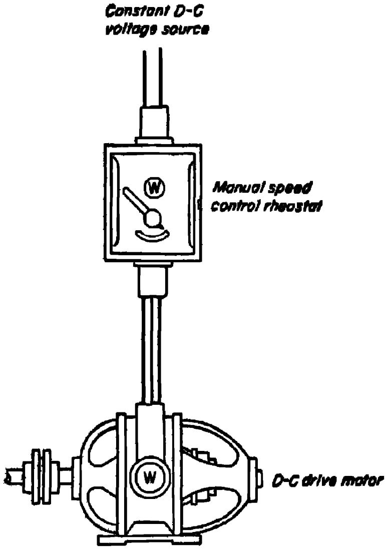

Fig. 16-9. Typical d-c drive consisting of a shunt motor and manually operated faceplate-type controller.

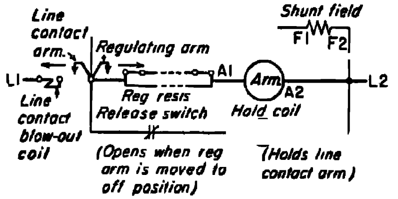

Fig. 16-10. Circuit diagram for a manual speed controller for speed adjustment by armature-resistance control.

The diagram for a typical manual controller which utilizes the apparatus illustrated in Fig. 16-9 is shown by Fig. 16-10. The motor is started by moving the control-rheostat handle in a counterclockwise direction. This movement closes the line contact, and the motor will start and accelerate to approximately 50 per cent of full-load speed if the load is correct for the resistors. A magnet energized by the "hold coil" will hold the line-contact arm in the closed position. The regulating arm may then be moved to short out the regulating resistor and to increase the speed by turning the handle in a clockwise direction. A star wheel and roller assembly on the operating-handle shaft provide positive positioning of the regulating-arm contacts on the stationary contact segments. The motor can be stopped by moving the regulating arm in the counterclockwise direction to the off position. The release switch opens just after the regulating arm is moved beyond the first or lowest speed point. Deenergization of the "hold coil" releases the line-contact arm and opens the circuit to stop the motor. As the line-contact arm is magnetically held in the closed position, this controller will provide low-voltage protection and always ensure that the motor is started with full resistance in the circuit. This type of controller usually does not provide any overload protection.

For armature-resistance control, the motor is almost always operated with full shunt-field excitation. Figure 16-11 shows typical speed-torque curves for a 10-point manual controller with a class 93 resistor for varying-torque applications. This resistor class provides 50 per cent speed reduction at not less than 35 per cent of full-load torque. The regulation of this drive is not very good as it varies from approximately 120 per cent at low speed to about 10 per cent at rated speed. Other intermediate speeds than those shown can be obtained by using more resistor steps.

Class 95 resistors are used for constant-torque applications and provide 50 per cent reduction in motor speed with not less than 80 per cent of full-load torque.

The speed–torque characteristic of a fan load is also shown on Fig. 16-11. When the line contact is closed, the motor will be accelerated on the first-point speed curve to the point indicated by *A*. When the regulating arm is moved to the second point, the motor will then increase in speed from point *B* to *C*. On the third point, the speed will change from *D* to *E*, etc.

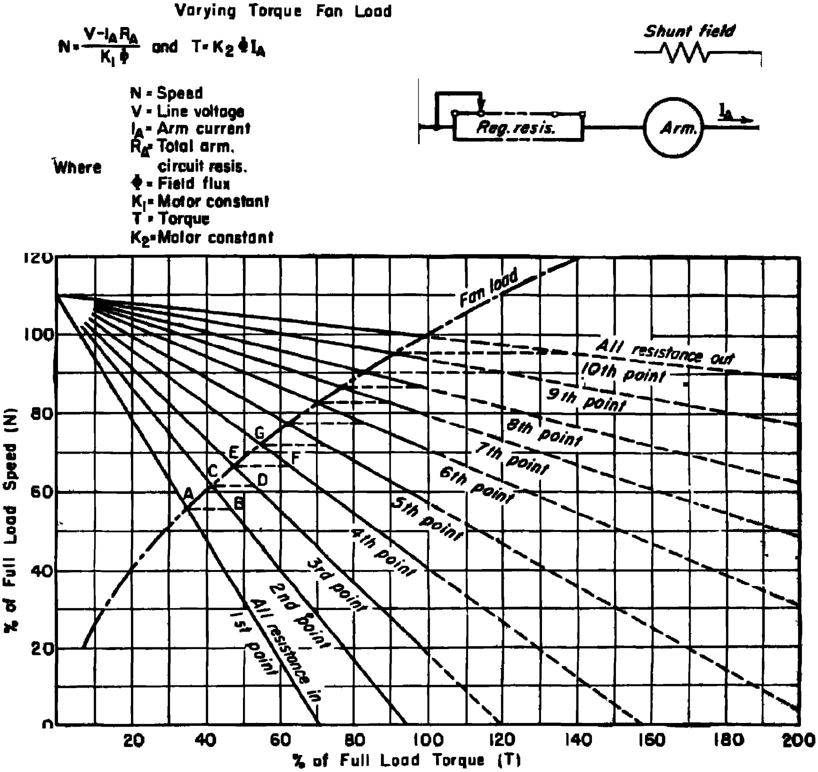

FIG. 16-11. Typical speed–torque curves for armature-resistance control of a d-c shunt motor. Class 93 resistor for varying-torque applications.

For speed reductions below 50 per cent of the rated speed (full-field excitation from rated voltage on the field), the armature is generally shunted by a resistor to improve the regulation and to reduce the differential between the no-load and full-load speeds. Figure 16-12 illustrates how the speed regulation can be greatly improved with the motor armature shunted. When the per cent of the impressed voltage on the armature is known, the per cent of base speed can be found for both no load and full load from the curve shown on Fig. 16-6.

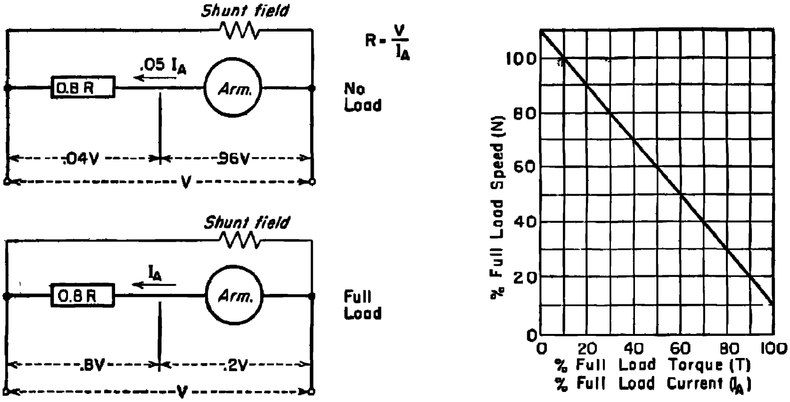
Speed Adjustment by Field-excitation Control.

SPEED RANGE:

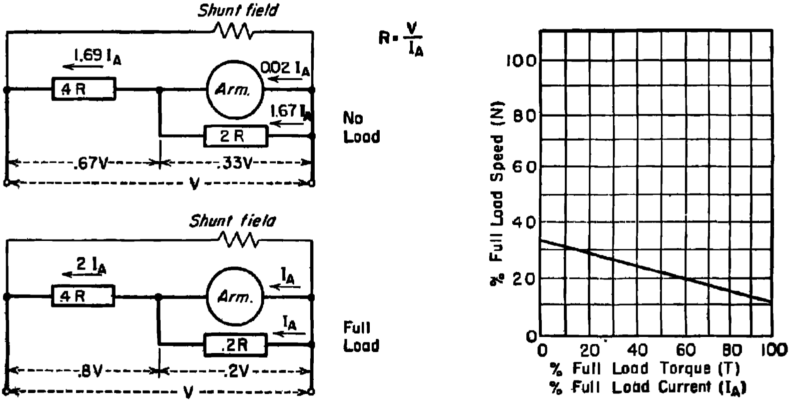
4:1 (4:1 speed increase by field control)

Speed Decrease from No Load to Full Load:
Approximately 10 per cent at base speed
Approximately 25 per cent at high speed
Horsepower:
Unlimited

An examination of the speed equation for a d-c shunt motor shows that the speed can be adjusted by varying the shunt-field excitation Φ. A rheostat in series with the field can be used to vary the field current. This in turn increases or decreases the excitation.



Armature Series Resistor



Armature Shunting Resistor

Fig. 16-12. Circuit diagrams and comparison of the regulation for a d-c shunt motor with a series or an armature-shunting resistor.

Figure 16-13 shows the apparatus required for a typical d-c drive with speed adjustment by field control.

Magnetically operated starters are advantageous over the manually operated type as they are more suitable for remote operation, interlocking, and providing overload protection. Figure 16-14 shows the circuit diagram for the drive shown in Fig. 16-13.

When the START push button is operated, the inductive accelerating contactor coil 1*A* will be energized. The main contacts 1*A* will open to permit the first step of the starting resistor to become effective, and the auxiliary contacts 1*A* will close to energize the second accelerating contactor coil 2*A*. The main contacts 2*A* will open, and the auxiliary contact 2*A* will close to energize the line-contactor coil *M*. Energization of coil *M* will close the line contacts *M*, and the motor will be started with reduced voltage on the armature.

The line-contactor auxiliary contact M_b also opens and deenergizes the coil 1*A* to initiate the time-delay period. After a time-delay period of several seconds, the main contacts 1*A* will close to short out step *R*1-*R*2 of the starting resistor. The auxiliary contacts 1*A* will also open to deenergize coil 2*A*. After another time-delay period, the main contacts 2*A* will close to short out all the starting resistor and to apply full voltage to the motor armature. The motor will continue to run until it is deenergized because of operation of the STOP push button, the overload relay, or a power failure.

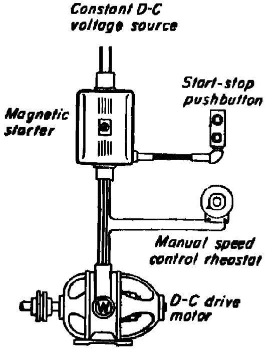


Fig. 16-13. Typical d-c drive consisting of a shunt motor, magnetic starter and push button, and a field rheostat.

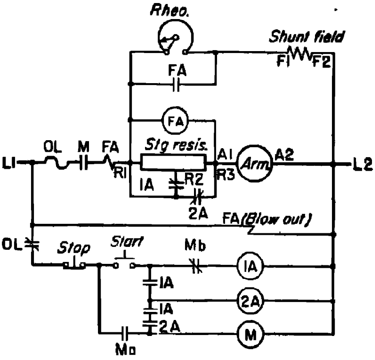

Fig. 16-14. Circuit diagram for speed adjustment of a d-c shunt motor by field control.

The field-accelerating relay *FA* is operated by a series and a shunt coil so that the motor is always started with full field. Also, full field is automatically applied when the motor current increases beyond a preset value. Full field is necessary to provide ample torque without excessive motor current for the load requirements.

After the motor has once been accelerated to a speed that corresponds to the speed for full line voltage on the motor armature, the contact *FA* in parallel with the field rheostat will open so that the rheostat will be effective to adjust the field current for speed control.

Figure 16-15 shows a family of curves for the speed-torque characteristic of a d-c drive motor with a 13-point field rheostat. Other intermediate speeds can be obtained by using a rheostat with smaller steps and a greater number of points.

The regulation is best at the base speed and increases as the speed increases. As this drive operates with a constant-horsepower characteristic, the safe drive torque available decreases as the speed increases. It should always be remembered that the motor will overheat if it is operated continuously at greater than rated full-load armature current. As the armature current I_A should not be increased above 100 per cent of the full-load value, the torque *T* value must decrease as the field flux Φ decreases for obtaining the higher speeds.

Speed Adjustment by Both Armature-resistance and Field-excitation Control.

SPEED RANGE:

8:1 (50 per cent speed reduction by armature-resistance control and 4:1 speed increase by field control)

SPEED DECREASE FROM NO LOAD TO FULL LOAD:
Approximately 50 per cent at low speed
Approximately 10 per cent at base speed
Approximately 25 per cent at high speed
HORSEPOWER:
¼ to 50

The speed adjustability of a d-c shunt motor drive can be greatly increased by using both armature-resistance and field-control means.

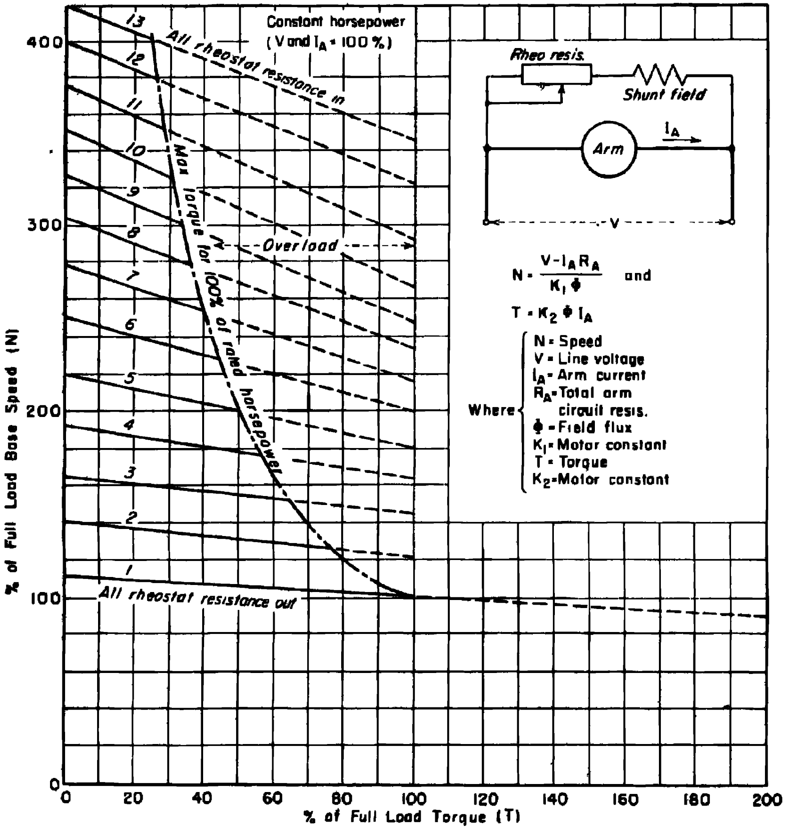

FIG. 16-15. Typical speed-torque curves for the speed adjustment of a d-c shunt motor by field control.

Figure 16-16 shows typical apparatus which can be used for this type of speed control. A drum controller functions similarly to the faceplate rheostat previously described, but it is more rugged and can be manufactured in much higher ratings than the faceplate type of starter and regulating controller. In general, the cost of a magnetic controller is higher than that for a drum type of controller. However, ease of operation, remote or automatic, and the possibility of interlocking features which are characteristic of magnetic controllers should always be considered in the selection of the apparatus for an electrical drive. Figure 16-17 shows a typical diagram for a five-point drum-type controller. The F contact on the drum opens only on the last or fifth point and ensures that the motor shunt field is always fully excited when reduced voltage is applied to the motor armature. When all the regulating resistor is shorted out, the field rheostat may be used to adjust the speed to a higher value. This particular controller does not have any provision for overload protection. This type of d-c drive falls in the constant-torque and constant-horsepower classification. The set of speed–torque curves shown in Fig. 16-18 illustrates the characteristics obtained from a drive which has five points of armature-resistance control and 17 points of field control. Intermediate speeds can be obtained by using a drum controller and a field rheostat with more points or steps. It should be noted that, for this drive, the speed regulation is best at the base speed.

FIG. 16-16. Typical apparatus for a d-c shunt-drive motor with speed adjustment by armature resistance and shunt-field control.

D-c Compound-wound Motor Drives. Compound-wound motors have both shunt and series fields, and the relative strength of the two fields determines to what extent the motor operation approaches the shunt- or series-motor characteristics. The formulas previously given for the counter emf, speed, and torque of a d-c shunt motor also apply in general to a compound-wound motor. A compound-wound motor provides a relatively high starting torque which approaches that of a series motor and yet has the desirable characteristics of a safe no-load speed which is typical of a shunt-wound motor.

From no load to full load, the drop in speed or regulation of a compound-wound motor is approximately 25 per cent for operation at full shunt-field excitation.

Compound-wound motors are used extensively on applications where a reasonably constant speed is required and where a motor must develop a high starting torque to accelerate the driven machine. This type of motor is extensively used on piston pumps, conveyors, compressors not equipped with unloading devices, mining and loading machines, and other similar applications.

In general, compound-wound motors are not recommended for adjustable-speed applications, as the weakening of the shunt field to obtain a speed increase changes the proportionate ratio of the shunt and series fields. Also, the speed characteristics of a motor operated with less than full excitation on the shunt field are similar to those of a series-wound motor with the series field shunted.

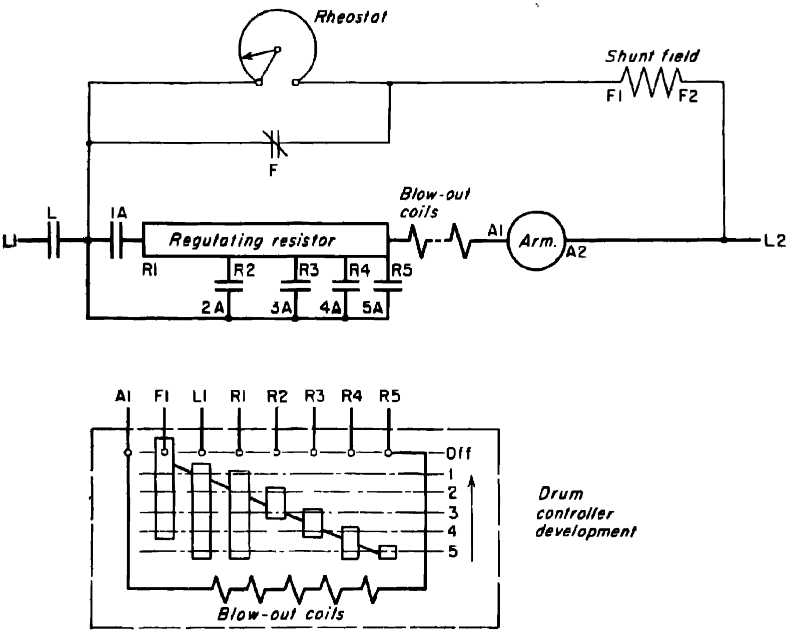

Fig. 16-17. Circuit diagram for speed adjustment of a d-c shunt motor by armature-resistance and shunt-field control.

Compound-wound motors have a speed-torque characteristic which is suitable for application to machines with flywheels or which have a high inertia-load characteristic as the motor drooping-speed trait will permit the flywheel to give up its kinetic energy if the load is suddenly applied. When a flywheel is permitted to give up its energy, the motor power requirements and the disturbances on the power supply are appreciably reduced. It also results in less heating of the motor.

Compound-wound motors can be started by the faceplate, drum, or magnetic type of controller which was previously described for shunt-wound motors.

D-c Series-wound Motor Drives. D-c series-wound motors are inherently varying-speed motors as the field winding is in series with the armature. Any change in the armature current will vary the field flux. This type of motor provides a relatively high starting torque with a relatively low starting current. Series motors are capable of starting and accelerating heavy loads with lower values of current drawn from the power supply than any other type of motor.

On light or no loads, the motor speed may be dangerously high since the series-field flux decreases as the armature current decreases. For this reason, series motors should be employed only where the load is never entirely removed from the motor or where close supervision is maintained. A series motor should never be connected by a belt to the load; it should always be connected by gears, chains, couplings, or some positive means.

Series-wound motors are applied mainly for widely varying loads, such as are typical for hoists, cranes, winches, etc., where wide speed changes are permissible and desirable. Sometimes series motors are provided with a shunt field which produces just enough field to prevent the motor from having an excessive speed on very light loads.

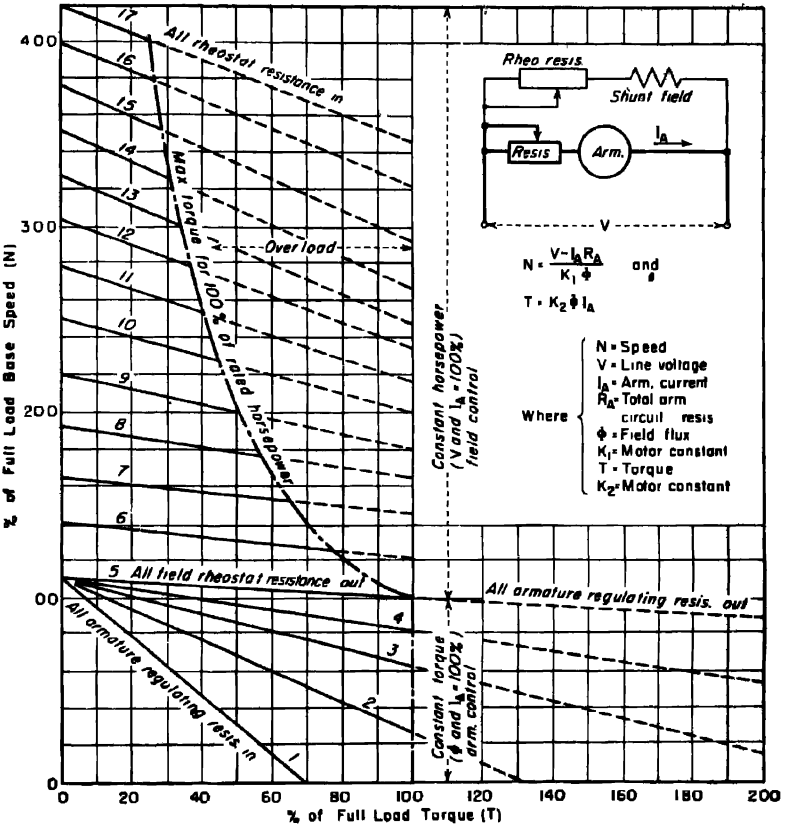

FIG. 16-18. Typical speed-torque curves for the speed adjustment of a d-c shunt motor by armature-resistance and shunt-field control.

While the general counter emf, speed, and torque equations given for d-c shunt motors also apply to series-wound motors, the only practical way to vary the speed is to vary the voltage applied to the armature and series field. Any attempt to control the series-field excitation separately would nullify the reason for using a series-wound motor in the first place.

Speed Adjustment by Armature-resistance Control.

SPEED RANGE:
Indeterminate (depends entirely on load)
SPEED DECREASE FROM NO LOAD TO FULL LOAD:
Approximately 100 per cent or more at low speed
Approximately 100 per cent or more at base speed
HORSEPOWER:
1 to 200 intermittent

Series motors are often controlled by manually operated drum controllers as that type of control provides a very rugged and compact control unit. Figure 16-19 shows the apparatus required for a typical d-c series-motor drive that is often applied to cranes or hoists.

D-C series drive motor

FIG. 16-19. Typical d-c series-motor drive with a protective controller.

Where ease of operation is required and a higher first cost of the controller can be justified, automatic magnetic control operated by a master switch is often used.

For some applications, such as encountered for large cranes or steel-mill drives, the motor currents that must be carried and interrupted are beyond the values that can be handled safely and efficiently by manually operated controllers; for such applications, only magnetically operated controllers are satisfactory.

Figure 16-20 shows a typical circuit diagram for a series-motor drive. For overload protection, limit-switch control, and interlocking, a protective panel with a line contactor *M* and an overload relay *OL* must be used. The line-contactor coil *M* is initially energized only in the drum OFF position through the RESET contact. The coil remains energized through its auxiliary contact M_a when the drum is moved to any other position. In case of a voltage failure or operation of the overload relay, the coil M is deenergized, and the contactor will then open the line contacts M to stop the motor. The motor can be restarted only by moving the drum controller to the OFF position. The protective panel prevents starting of the motor unless all the starting and regulating resistance is in series with the motor armature and series field.

Figure 16-21 shows typical speed–torque curves for a series-motor drive. From this set of curves it should be noted that the series motor has an excessive speed characteristic when the motor has a very small load.

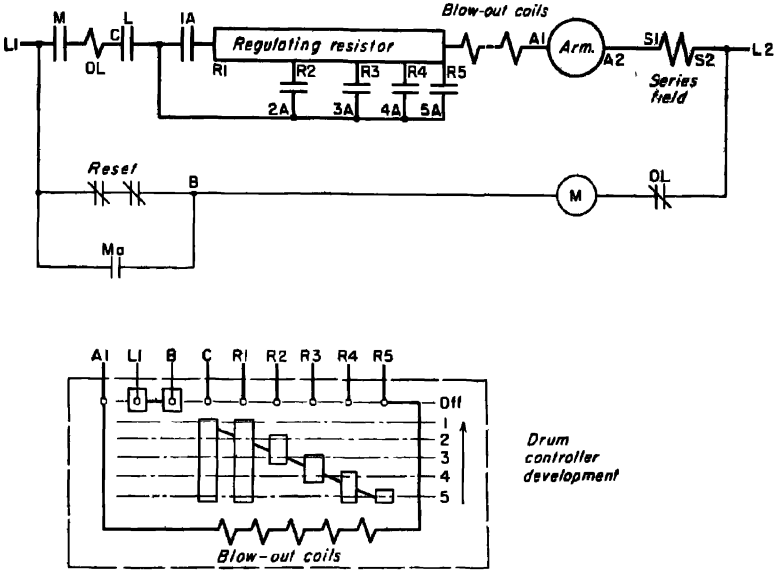

FIG. 16-20. Circuit diagram for a d-c series motor with speed adjustment by armature-resistance control.

Comparison of Typical D-c-motor Characteristics. Figure 16-22 shows the comparison of the typical speed, current, torque, and horsepower characteristics for shunt-, compound-, and series-wound motors operated at their base speeds. It should be noted that the current–horsepower curves are plotted to a different ordinate scale as they would otherwise obscure the current–torque curves. The careful consideration of this curve should be very helpful in the selection of the drive motor which has the proper speed, regulation, torque, etc., characteristics.

Graphical Analysis for the Selection of a D-c Shunt-wound Motor Drive. In selecting the proper drive for a specific application, the speed range, size, cost, regulation, etc., must be considered. Figure 16-23 illustrates how to analyze a typical application where it is desired to apply a d-c shunt-wound motor to a constant-torque load which requires a 4:1 speed range or speed adjustment from 450 to 1,800 rpm. The speed–torque and speed–horsepower requirements of the load are plotted in Col. *a* of Fig. 16-23.

Column *b* shows the application of a constant-speed shunt-wound motor with 75 per cent base-speed reduction by armature-resistance control. While this drive meets the torque requirements of the load and is the lowest in cost, it should be borne in mind that the speed regulation for this type of drive is very poor compared to other drives, and the number of speed points is limited. Standard drives with speed adjustment by armature-resistance control are usually recommended for only 50 per cent speed reduction. However, by using an armature-shunting resistor on the lower speed point and carefully selecting the motor, it is possible to obtain the desired speed reduction.

Column *c* of Fig. 16-23 illustrates the characteristics of a drive with a constant-speed motor with speed adjustment by both armature-voltage and field control. From

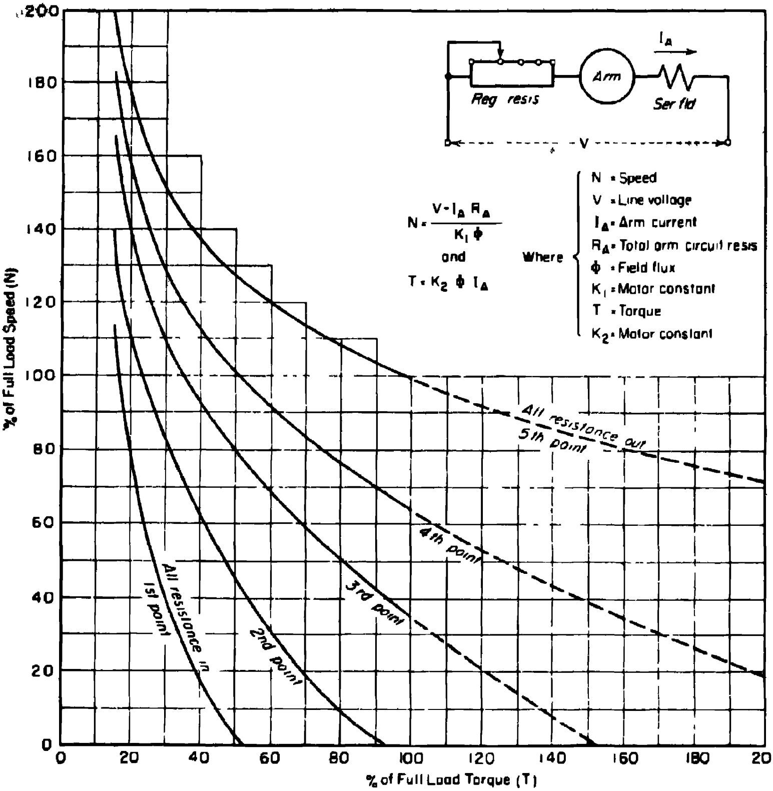

FIG. 16-21. Speed–torque curves for a d-c series motor with speed adjustment by armature-resistance control.

the curve it should be noted that the armature-regulating resistor needs capacity for only 40 per cent of the rated horsepower at the base speed.

Column *d* shows a drive which has an adjustable-speed motor that will provide a 4:1 speed adjustment by control of the shunt-field excitation only. This drive gives a fairly good speed regulation and provides a relatively large number of points. The cost of this particular drive is considerably higher than the other two, and it should be noted that the full horsepower rating of the motor can be utilized only when the motor is operated at the maximum speed required by the load. The weight and size of this particular drive are larger than those of the other drives considered.

As a general rule, it should be remembered that, the higher the shunt-motor base speed, the smaller the motor-frame size and the lower the motor cost. It is recommended that a graphical analysis similar to the one discussed always be made in order to obtain the most economical and satisfactory drive.

A-C MOTOR DRIVES—A-C POWER SOURCE

The electrical energy distributed in the United States today is predominantly 60-cycle alternating current. For this reason it is generally more economical to apply a standard a-c motor and controller to the application if it provides suitable drive characteristics.

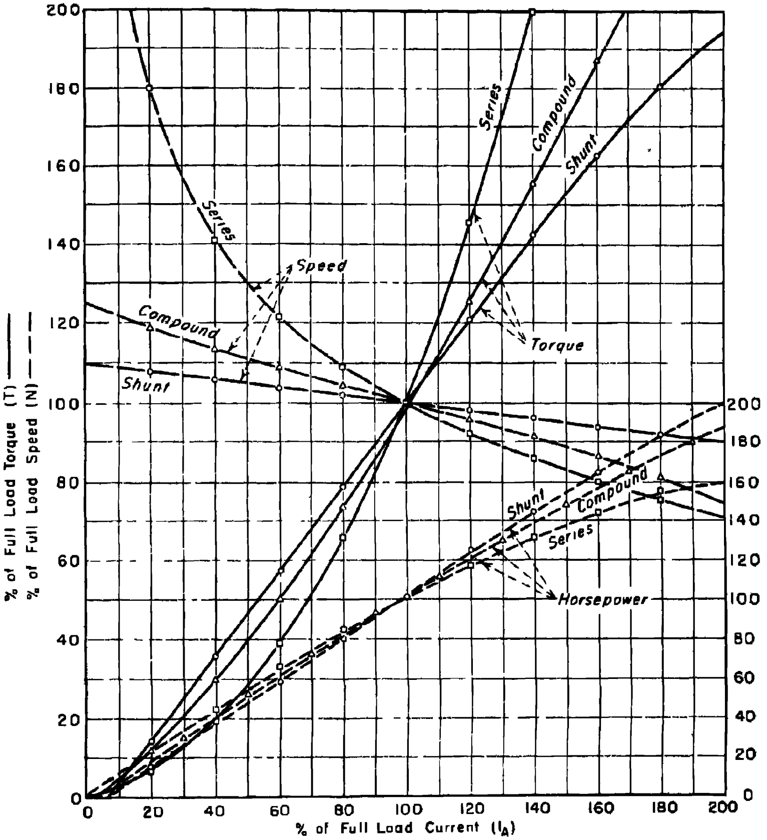

FIG. 16-22. Comparison curves of the d-c shunt-, compound-, and series-wound-motor characteristics.

A-c-motor Basic Speed Formula. The speed of an a-c motor is determined by the number of poles in the field winding and by the frequency of the applied voltage to these windings. The basic equation for the "synchronous" or maximum theoretical speed in terms of the number of poles and the frequency can be expressed by the following formula:

$$N = KF/P$$

where N = synchronous speed
K = constant
F = frequency of power supply
P = number of poles

When the speed N is expressed in rpm and the frequency F in cycles per second, the constant K is equal to 120.

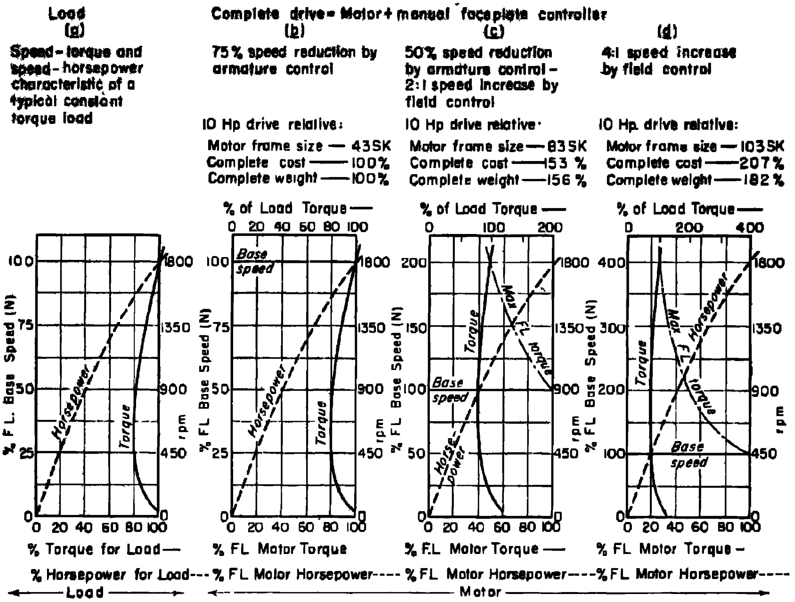

FIG. 16-23. Graphical analysis of three different speed-control methods for a typical constant-torque load.

Except for an a-c synchronous motor, the synchronous speed is a theoretical speed which a motor could attain only if it had no losses or load. An a-c induction motor can never reach synchronous speed as there is no torque developed when the rotor revolves at exactly the same speed as the rotating field. The difference between the synchronous speed and the actual speed for the torque that is required to drive the motor and the load is called the "slip." The speed of an induction motor is also determined by the load requirements and will be a speed at which the motor-torque output and the load-torque requirements are exactly in equilibrium.

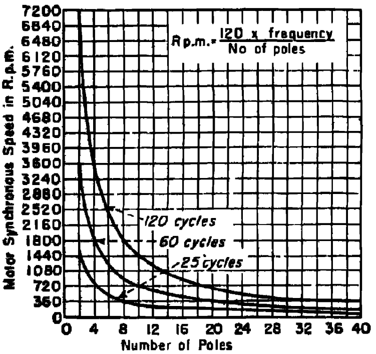

FIG. 16-24. Relationship between speed and the number of poles for a-c motors operated at given frequencies.

As shown by the speed equation, the motor speed can be varied by changing the frequency of the power supply or the number of poles in the field winding. It should always be borne in mind that an a-c motor must always have an even number of poles (same number of North as South poles), and the minimum number of poles is two. Figure 16-24 graphically shows the relationship between the speed and the number of poles at given frequencies of 25, 60, and 120 cycles.

Figure 16-25 graphically shows the speed of a motor with a given number of poles for frequencies up to 120 cycles. It should be noted that, for a speed change by adjustment of the frequency, the change in speed per cycle is greatest for a two-pole motor and least for a forty-pole motor.

A more complete table of the synchronous speeds for various pole and frequency combinations is given by Fig. 16-26.

A-c-motor Basic Torque Formula. In general and except for some conditions of synchronous-motor operation, the torque developed by an a-c motor is proportional to the square of the impressed voltage V applied to the stator or field windings. The approximate torque equation can be expressed as follows:

$$T = KV^2$$

where T = torque
K = motor design and conversion constant
V = voltage applied to the field or stator windings

The speed of an a-c induction motor can be controlled to some extent by adjusting the voltage applied to the field windings. As a variation in the applied voltage will change the torque output of the motor, the speed of the motor must change for a given load. This method of speed control is not too satisfactory for general application, as a reduction in the applied voltage may result in a very low breakdown torque. For some single-phase fan applications, this method of control is quite widely used and satisfactory, as the load characteristic is such that the horsepower requirements decrease rapidly with a decrease in speed.

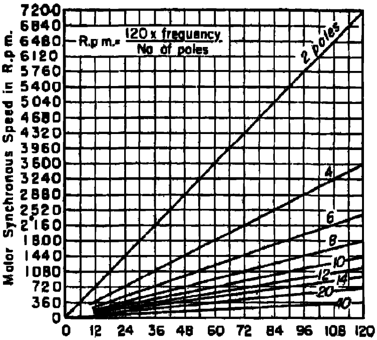

Fig. 16-25. Relationship between speed and the frequency applied to an a-c motor with a given number of poles.

No. of poles	Motor Synchronous Speeds in R.p.m. for Frequencies of							
	25~	50~	60~	90~	120~	180~	360~	420~

Fig. 16-26. Motor synchronous speeds for various frequencies and pole combinations.

A-c Squirrel-cage Induction-motor Drives. Alternating-current squirrel-cage induction motors are considered to be the simplest and sturdiest of the electrical rotating devices that are now manufactured.

In the field of integral-horsepower motors, the polyphase induction motor is predominantly the most widely used type of motor applied to constant-speed industrial drive applications. Also, polyphase a-c power is usually the only type of power available at the majority of the industrial sites.

In the field of fractional-horsepower motors, the single-phase induction motor is the most widely used type of motor. In general, polyphase power is not usually available at the places where the majority of the fractional-horsepower motors are applied.

Squirrel-cage induction motors are essentially constant-speed motors, and in general, no relatively inexpensive control methods are known by which a reliable speed change and control may be obtained on a motor of a relatively large size. About the only practical means available for varying the speed of a relatively small induction motor without changing the number of poles or the frequency of the power supply is to adjust the voltage applied to the motor field and permit the load to govern the speed at which the motor will then operate with a change in the output torque.

Speed Adjustment of a Single-phase Squirrel-cage Capacitor Motor by Primary Voltage Control (Autotransformer).

Speed Range:
  Approximately 2:1 or 3:1 (50 to 33 per cent speed reduction by voltage control)
Speed Decrease from No Load to Full Load:
  Approximately 70 to 50 per cent at low speed
  Approximately 5 per cent at base speed
Horsepower:
  Fractional

Figure 16-27 shows the apparatus required for a typical single-phase drive motor for a fan application. The control for this drive is manually operated and provides a means for varying the voltage applied to the motor.

The diagram for the drive illustrated in Fig. 16-27 is shown in Fig. 16-28. When the line contact M is closed, the motor will be connected to a tap on the autotransformer. The speed for a particular voltage will be determined directly by the load.

From the speed-torque curves shown in Fig. 16-29, it should be noted that the curve for the lowest value of voltage applied to the motor field windings has a very steep characteristic and a slope similar to the load at the lower speeds. The speed at which the motor and the load torques are in equilibrium will be very indefinite unless the load requirements are known quite accurately. The set of curves in Fig. 16-29 illustrates how four different fan-operating speeds can be obtained quite efficiently. This type of drive is successful only because the fan-load characteristics are such that the torque requirements fall off quite rapidly with a decrease in speed.

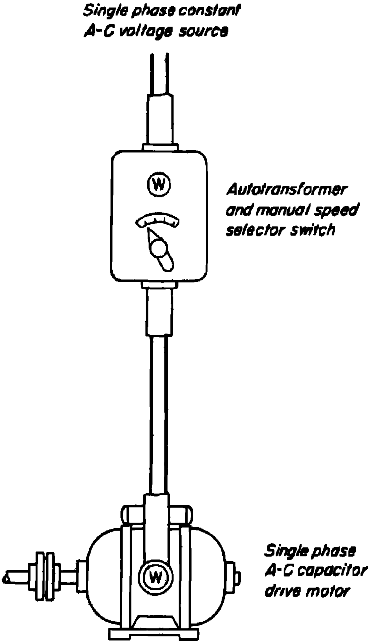

Fig. 16-27. Single-phase a-c capacitor-motor drive with speed adjustment by primary voltage control.

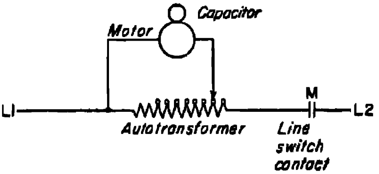

Fig. 16-28. Circuit diagram for a single-phase manually operated controller for speed adjustment by primary voltage control.

Typical Three-phase A-c Squirrel-cage Drive-motor Characteristics. For a given a-c squirrel-cage motor, the speed-torque characteristic is determined primarily by the rotor design and resistance. Linestart Class I and II motors operate at a relatively constant speed and differ primarily in the starting torque that each can develop.

High-torque high-slip motors have a drooping speed-torque characteristic which can be very effectively utilized for providing automatic speed control for applications where the load is pulsating and has load peaks of very large magnitude. As the motor speed automatically decreases quite rapidly with an increase in the load, the flywheel or mass of the driven machinery is permitted to give up its kinetic energy to the load. As the energy is supplied by the inertia of the rotating system, the motor-current peaks and power-supply disturbances are reduced to a minimum when this type of motor is applied to a pulsating load such as encountered in a punch press, crusher, etc. A normal or low-slip (Class I or II) motor is not generally satisfactory as a high-torque

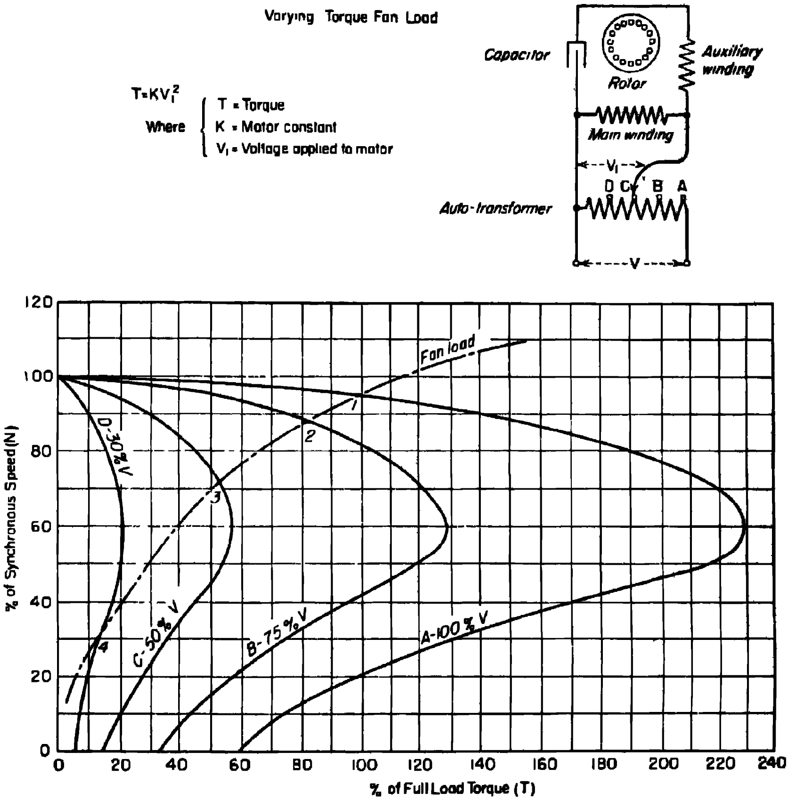

FIG. 16-29. Typical speed-torque curves for primary voltage control of a single-phase capacitor motor.

cyclic load would also probably seriously overheat the motor. These characteristics are shown in Fig. 16-30.

This example illustrates why it is very important to select the most suitable motor, as automatic speed control can be obtained very simply and at a relatively low cost.

Speed Adjustment of a Three-phase A-c Squirrel-cage Drive Motor by Primary Voltage Control (Primary Resistor).

SPEED RANGE:

From full speed to 0 speed with operation at very indefinite speeds

SPEED DECREASE FROM NO LOAD TO FULL LOAD:

Approximately 100 per cent at low speed

Approximately 3 to 4 per cent at high speed

HORSEPOWER:

Not practical except for very low ratings and variable-torque loads

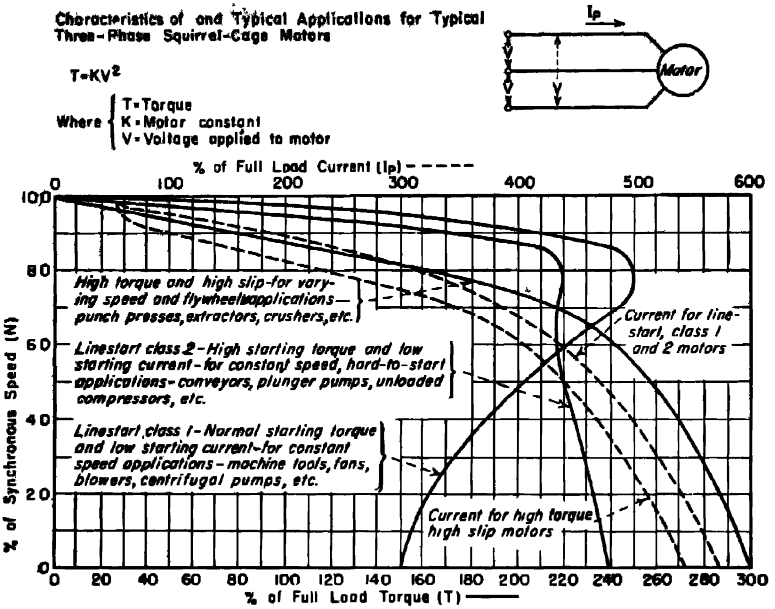

FIG. 16-30. Typical speed–torque and speed–current curves for three-phase a-c squirrel-cage motors.

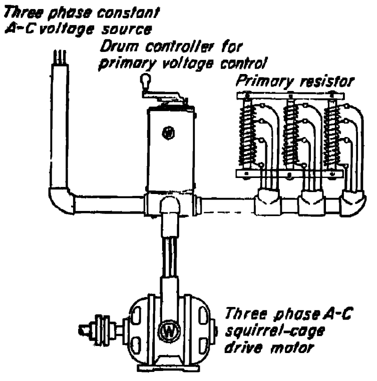
The output torque of a squirrel-cage induction motor can be controlled by inserting resistance in each phase of the primary circuit to reduce the voltage actually applied to the field windings. Figure 16-31 shows a three-phase squirrel-cage motor drive with a manually operated primary-resistor controller for adjusting the motor torque.



Three phase constant A-C voltage source
Drum controller for primary voltage control
Primary resistor
Three phase A-C squirrel-cage drive motor

FIG. 16-31. Three-phase a-c squirrel-cage motor drive with speed adjustment by primary voltage control.

The circuit diagram for a primary-resistor controller with a manually operated drum is shown by Fig. 16-32. When the drum-controller handle is moved to the first point, the motor is energized with all the resistance in series with each phase. The speed will be determined only by the torque requirements of the load.

Figure 16-33 shows typical speed–torque curves for a four-point manual controller. It should be noted that, for this particular resistor design, the speed can be varied only in a very small range, or from approximately 75 to 95 per cent for a varying-torque load.

For the constant-torque load shown, the motor can be started only on the fourth point or with full voltage on the motor. After the motor is once started, the speed can be reduced to only 90 per cent of the synchronous-speed value by moving the drum back to the second point.

This particular type of controller was illustrated only to show that, for general application, this means of speed control is very ineffective and not satisfactory. This type of control also has another undesirable feature, as the drum controller must be capable of carrying and interrupting relatively large primary currents.

FIG. 16-32. Circuit diagram for a three-phase manual speed controller for speed adjustment by primary voltage control.

Speed Adjustment of Three-phase A-c Squirrel-cage Multispeed Drive Motors by Pole-changing Control.

SPEED RANGE:
  Single-winding motors 2:1
  Multiple-winding motors 2:1, 3:1, 4:1, etc.
SPEED DECREASE FROM NO LOAD TO FULL LOAD:
  Approximately 3 to 4 per cent
HORSEPOWER:
  Unlimited

The basic speed equation given for a-c motors also shows that, for a given frequency, the speed can be varied by changing the number of poles in the motor field windings. Multispeed motors are constructed so that it is possible to reconnect the windings to provide two or more pole combinations.

Figure 16-34 shows typical connection diagrams for two- and four-speed motors. It is not practically possible to obtain any speed adjustment between the synchronous speeds for the various pole combinations, but this type of motor is widely applied to fans, machine tools, etc., where only two, three, or four different speeds are entirely satisfactory.

It should be noted that three speeds can be obtained by using only three pole combinations of a four-speed motor assembly. On motors with two or three separate windings, all the individual windings that are not in use to obtain a certain pole combination are generally open-circuited to prevent circulating currents from being induced in those windings.

For two-speed motors with single windings, the ratio between the high and low speeds is always 2:1. Standard two-speed two-winding motors can have almost any high-speed to low-speed ratio, such as 1.33:1, 1.6:1, 2:1, 2.66:1, 3:1, 4:1, etc.

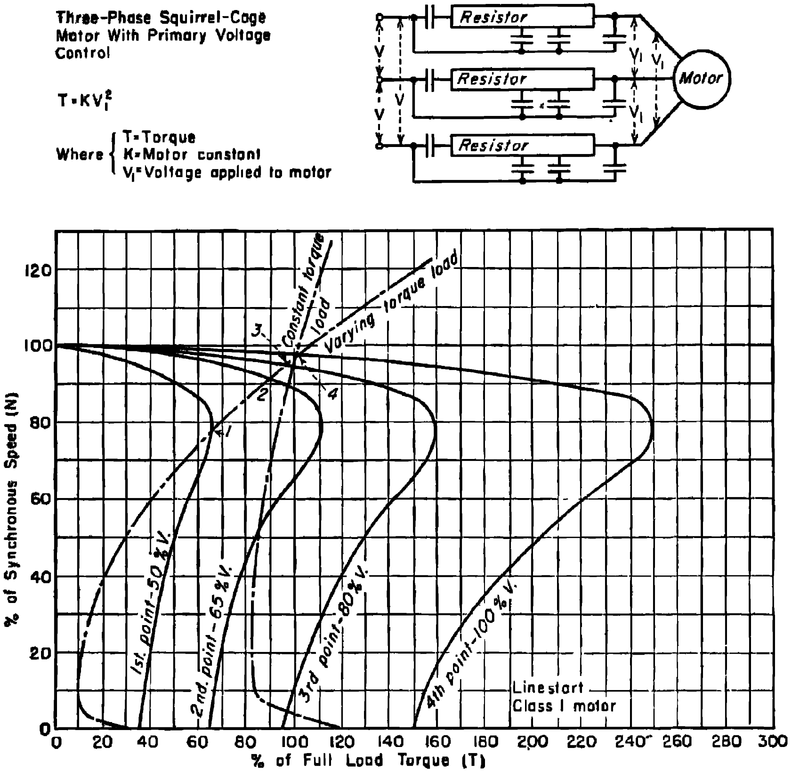

Fig. 16-33. Typical speed–torque curves for a three-phase squirrel-cage motor operated with resistance in the primary circuit.

Three- and four-speed motors can have numerous pole combinations which will provide a relatively large range in the speed ratios.

For the most satisfactory selection of a multispeed drive motor, the exact characteristics of the load must be accurately known. A comparison of the horsepower ratings and physical size of 10-hp constant-horsepower, constant-torque, and variable-torque motors is shown in Fig. 16-35. A variable-torque motor cannot be applied to a constant-horsepower load as it would overheat at the lower speeds. A constant-horsepower motor could be applied and could handle any of the three types of loads, but it would be very uneconomical for constant- and variable-torque loads as the motor would be much larger in size than necessary, have excess thermal capacity at the lower speeds, and cost considerably more than the motor that has just the right capacity for the load.

Figure 16-36 shows a typical multispeed motor drive with a manually operated speed-selector station and a magnetically operated pole-changing starter.

Manually operated drum switches are also available for multispeed-motor control. This type of control does not generally provide any means for interlocking or overload protection.

Typical two-speed magnetic-starter diagrams are shown in Fig. 16-37. For these particular circuits the motor can be started and operated for either speed depending upon the push button operated. When a push button is operated, its respective speed-contactor coil is energized, and the main contacts close to start the motor to operate ultimately at the desired speed. It is not necessary in this circuit to hold the push button down as an auxiliary interlock contact will close to provide continuous energization of the coil when the push button is released. The push buttons are interlocked so that operation of the other speed push button will deenergize one contactor coil and energize the other coil for the desired speed.

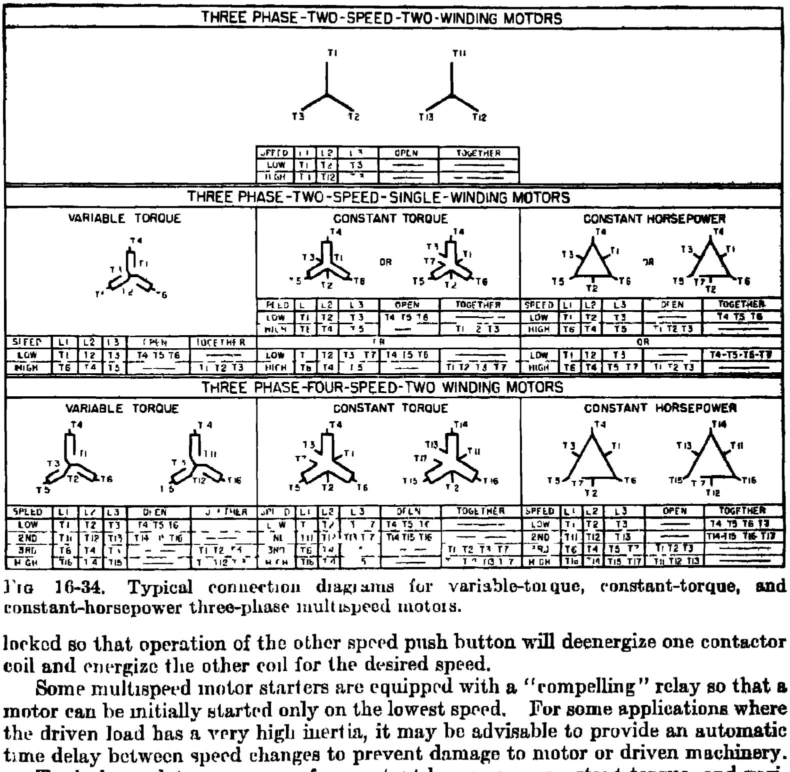

Fig 16-34. Typical connection diagrams for variable-torque, constant-torque, and constant-horsepower three-phase multispeed motors.

Some multispeed motor starters are equipped with a "compelling" relay so that a motor can be initially started only on the lowest speed. For some applications where the driven load has a very high inertia, it may be advisable to provide an automatic time delay between speed changes to prevent damage to motor or driven machinery.

Typical speed-torque curves for constant-horsepower, constant-torque, and variable-torque motors are shown in Fig. 16-38. It should be noted that the full-load torque for the lowest speed of a constant-horsepower motor must be twice the value of the high-speed torque. It is also two times the value of that for the low speed of a constant-torque motor and four times that of a variable-torque motor. The curves in Fig. 16-38 are based on motors that have the same rating at the highest speed and have a high- to low-speed ratio of 2:1. For motors with two separate windings, the ratio between the high and low speeds does not necessarily need to be 2:1.

Bearing in mind that the hp = TN/K (where hp = horsepower, T = torque, N = speed, and K = a conversion constant), this set of curves graphically illustrates the data tabulated in Fig. 16-35.

A-c Wound-rotor Induction-motor Drives. The limited capacity of the power systems in the early days when induction motors were first developed and applied forced the extensive use of wound-rotor motors to keep the starting currents to a minimum. As squirrel-cage motors were developed and perfected and the capacity of the power systems was greatly increased, the squirrel-cage type of induction motor supplanted the wound-rotor type of motor for the majority of the a-c-motor applications.

However, there are still several types of applications where the wound-rotor type of motor is preferable over any other type of a-c motor. First, the wound-rotor induction motor is well adapted to applications where particularly high starting torques and low starting currents are required simultaneously. Pumps, compressors, and other continuous-duty and constant-speed applications are often driven by wound-rotor motors.

The second major type of application for the wound-rotor induction motor is where speed adjustment is required. This type of motor is often applied for driving fans and conveyors that require speed adjustment and when only a-c power is available. With special control equipment, wound-rotor motors have been very successfully applied to cranes and hoists.

FIG. 16-37. Typical diagrams for a two-speed motor with speed adjustment by pole-changing control.

The inherent characteristics of a wound-rotor induction motor are such that, with resistance in the secondary circuit, the driven load will directly determine the motor speed. The motor slip depends almost entirely upon the load, and if the load is removed, the motor speed will approach the maximum synchronous value. In general, wound-rotor motors should not be applied where it is expected that very low speeds at very light loads will be required. Under these conditions the operation may not be very satisfactory unless a very costly investment is made in special resistors; for many applications this extra cost is not practicable or feasible. Usually, a

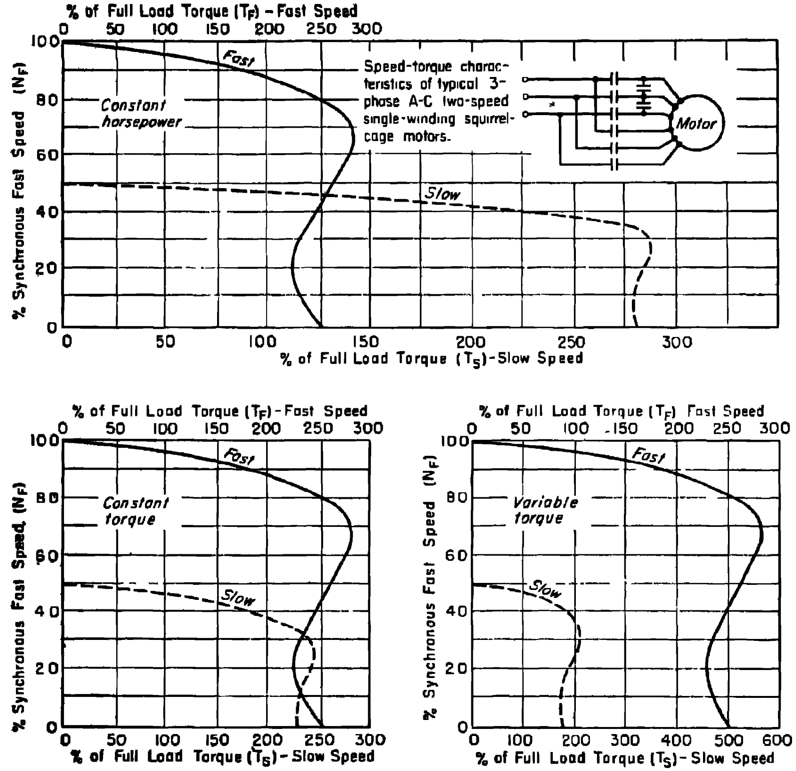

FIG. 16-38. Comparison of the speed-torque characteristics of typical multispeed squirrel-cage motors.

50 per cent speed reduction is considered to be the maximum reduction that should be required from this type of motor if stable operation is desired. Special control equipment, artificial electrical loading means, etc., are sometimes used to obtain stable operation at low speeds and useful light loads.

A manually operated starting and speed-regulating rheostat is generally the simplest type of controller for a wound-rotor motor. Figure 16-39 shows a typical wound-rotor drive motor with a magnetically operated primary starter and a manually operated secondary controller. Motor-operated drums, magnetically operated contactor controllers, or liquid slip regulators are generally used for the relatively large wound-rotor motors.

The circuit diagram for a typical manually operated starter and speed-regulating rheostat is shown in Fig. 16-40. The rheostat is arranged so that the motor is always started with all the resistance in the secondary circuit. A control contact on the faceplate arm momentarily provides a circuit for energizing the primary-starter contactor coil. Energization of this coil will close the contacts *M* and energize the primary circuit of the motor. The motor will then operate at a speed depending upon the load and the value of the resistance in the secondary circuit.

This circuit will provide low-voltage protection and make it necessary for the controller always to be returned to its OFF position before the motor can be restarted in case of an overload or voltage failure. Normally, the motor is stopped by returning the controller handle to the OFF position which will deenergize the line-starter coil *M*.

Main and control arms insulated and mechanically connected together.

FIG. 16-40. Circuit diagram for a three-phase wound-rotor drive motor with secondary resistance control.

A typical set of speed–torque curves for a seven-point secondary resistor controller is shown by Fig. 16-41. These curves are similar to those which would be obtained from a resistor designed according to the specifications for a NEMA class 93 resistor for varying-torque applications. With these resistor values, on the first point the motor will develop approximately 35 per cent of its rated torque and will operate at approximately 50 per cent of synchronous speed if the load is correct.

For some applications where "softer" starting and a finer speed control are required, special control is sometimes arranged so that one phase of the secondary circuit is opened. For single-phase operation, the motor will develop only about 50 per cent of the three-phase starting torque.

It should be noted that, within certain operating regions, the speed–torque curves of a wound-rotor motor with secondary resistance control are very similar to those of the d-c shunt motor operated with resistance in the armature circuit (see Fig. 16-11).

A-c Synchronous-motor Drives. An a-c synchronous motor operates at absolutely synchronous speed. This characteristic makes it indispensable for many applications that must be operated at a constant speed. However, there are no very simple or inexpensive means available for varying the speed.

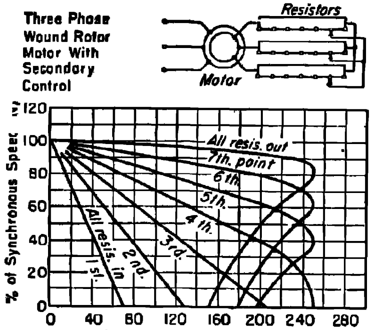

FIG. 16-41. Typical speed–torque curves for a three-phase wound-rotor motor with secondary resistance control.

Synchronous motors also operate according to the same unescapable relationship expressed by the speed equation previously given for a-c motors. The synchronous speed can be changed only by adjusting the frequency or changing the number of poles. Unless a number of synchronous motors are required for a particular application, it is not practical to provide an adjustable-frequency power system. Synchronous motors are sometimes arranged so that the windings can be connected for several different pole combinations.

The synchronous type of a-c motor is quite widely applied today as, in addition to providing a constant speed, it can also provide some power-factor correction for a power system.

Compared to the other starters for various types of a-c motors, the synchronous-motor controller is a little more complicated as it must control and synchronize both the a-c and d-c circuits.

A-C AND D-C UNIVERSAL-MOTOR DRIVES—A-C OR D-C POWER SOURCES

The universal motor is a series-wound and commutator type of motor which can be operated on either a-c or d-c power supplies. The performance and operating characteristics are essentially the same when it is operated on either type of power supply. The speed–torque characteristic curve is similar to that for a d-c series-wound motor.

This type of motor provides a relatively large starting torque and may have a no-load speed as high as 10,000 or 20,000 rpm. It is customarily built in fractional-horsepower sizes, and the armature is designed and constructed in such a manner that it can be operated at these high speeds safely. Some degree of speed control can be obtained on this motor by a series resistor or by the use of a tapped series field.

This type of motor has found wide application in electric adding machines, cash registers, drills, hammers, vacuum cleaners, motion-picture projectors, sewing machines, and other built-in applications where the motor housing is an integral part of the machine or appliance.

Universal motors have laminated armatures and stators so that they will operate satisfactorily on either a-c or d-c sources. For a given motor assembly, the armature will rotate in the same direction on either alternating current or direct current. When this type of motor is operated on alternating current the direction of the current in the armature circuit and the direction of the series-field flux reverse simultaneously; therefore, the average torque output always has the same direction.

Speed Adjustment and Control of a Universal Motor by a Centrifugally Operated Governor.

Speed Range:
Approximately 12:1 (or 500 to 6,000 rpm for one particular and typical governor design. Other governor assemblies can be used to provide other speed ranges)
Speed Variation from No Load to Full Load:
Approximately ±2 per cent
Horsepower:
$\frac{1}{50}$ to $\frac{1}{10}$

By means of a centrifugal-governor assembly mounted on the shaft, the universal motor can be adapted to provide a constant speed–torque characteristic from no-load to approximately 150 per cent of full-load torque. A typical universal drive motor with a centrifugal governor for speed adjustment and control is shown by Fig. 16-42. An adjusting screw on the governor assembly is provided for varying the constant output-speed value and is accessible only when the motor shaft is at standstill. Some governor assemblies are arranged so that the motor speed can be adjusted while the motor is running.

Figure 16-43 shows a diagram for a typical universal-motor drive. When the handle of the manual switch is moved to the ON position, the line contacts *M* will close and energize the motor. When the motor armature accelerates to a preset speed, the governor contacts will open and insert a resistor in series with the motor armature and field. The insertion of the resistor will prevent a further increase in speed. When the motor speed drops to a certain value, the governor contacts will reclose, and the motor will be again accelerated to the preset speed. This same type of control could be obtained by opening the circuit completely and omitting the resistor. However, more satisfactory operation can be obtained by inserting the resistor into the circuit to reduce the motor torque. The capacitor is connected in parallel with the governor contacts to improve the contact life.

Fig. 16-42. Typical universal-motor drive with a speed-control governor.

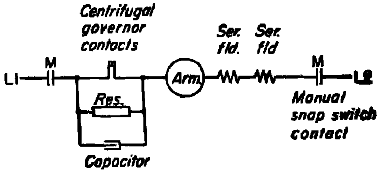

Fig. 16-43. Circuit diagram for a universal-motor drive with a centrifugal governor for speed adjustment and control.

When a universal motor with this type of control is in operation, the governor contacts open and close very rapidly, at approximately 100 to 200 times per second depending upon the natural resonant frequency of the moving contact. The contact vibration is thought to be maintained by the explosive force of the arc. The centrifugal force on the contact assembly tends to hold the contacts in the closed or open position depending upon the speed.

Figure 16-44 shows a comparison between the speed–torque curves for an universal motor with and without a governor for adjusting and maintaining the output speed constant. For a governor-controlled motor the extremely high speed characteristic is eliminated, and the speed is maintained at a constant value regardless of a change in the voltage, frequency, or load. This type of drive has been very successfully and economically applied to electric typewriters, calculating machines, motion-picture cameras and projectors, etc.

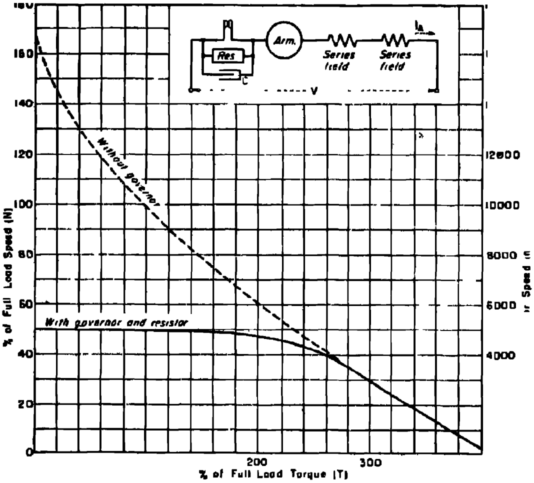

FIG. 16-44. Comparison of typical speed–torque curves for a universal motor with and without a speed governor.

D-C MOTOR DRIVES—A-C POWER SOURCE AND CONVERSION EQUIPMENT

Despite the fact that the electrical energy distributed in the United States today is predominantly 60-cycle alternating current, more d-c drives are being applied than ever before. For all the simplicity and inherent advantages of the a-c system, no a-c drives have yet been developed which are readily adjustable over the wide speed range which is now attainable with certain d-c drives. The popularity of the adjustable-speed d-c drives is steadily increasing because the versatility of the basic adjustable-voltage system has been increased by important new modifications and arrangements.

Some recently developed drives are very simple but have some limitations; other systems, more complex, provide possible speed ranges as great as 120:1. The d-c drive motor is unequaled for speed range and flexibility of control. The basic speed equations and motor characteristics have been discussed in previous sections and should be referred to for a more complete description of the principle or combination of principles utilized to obtain economical and flexible adjustable-speed drives.

Adjustable-speed drives are extensively used for paper mills, rubber-mill machinery, winders, machine-tool drives, hoists, and other similar applications.

Some adjustable-speed drives provide regenerative braking. This is an important feature which should always be considered when the drive is large. No emphasis has been placed on this feature in the following sections as speed control is the main subject.

While the cost of an adjustable-speed drive operating from an a-c power source is relatively high, it has been very widely used. It is now used for motors as small as 1 hp and even for fractional-horsepower motors in some cases. The additional first cost of this type of drive can often be saved in the design of the driven machine by the elimination of gears, cone pulleys, belts, and other complicated mechanisms.

D-c Series Adjustable-voltage Drives.

Speed Range:
10:1 (90 per cent speed reduction by armature-voltage control)
Speed Decrease from No Load to Full Load:
Approximately 15 per cent at low speed
Approximately 25 per cent at base or top speed
Horsepower:
Up to 15

An adjustable-speed drive utilizing a series generator and motor is one of the simplest means so far developed for obtaining adjustable-speed operation over a wide speed range from an a-c power source.

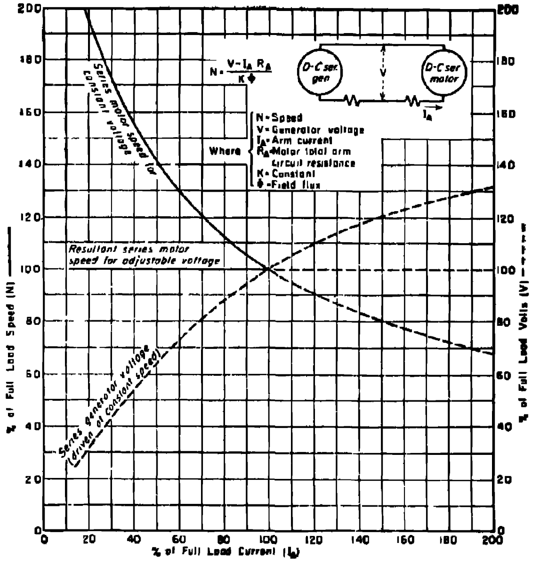

Fig. 16-45. Idealistic speed characteristic of a series motor operated in series with a series generator.

The basic speed equation for a d-c series motor shows that the predominant factors in the resultant motor speed are the value of the voltage applied to the armature and the magnitude of the field. Figure 16-45 illustrates the idealistic speed–current characteristic of a series motor operated from a series generator. The low voltage of the series generator at small values of current limits the inherently high no-load speed of a series motor; and the relatively high voltage of the series generator at high currents increases the normally low speed of a series motor which is heavily loaded.

The apparatus required for a typical series drive of this type is shown in Fig. 16-46. The d-c series generator is usually driven at constant speed by an a-c squirrel-cage induction motor. This drive has been very successfully applied to applications requiring a wide speed range with reasonably good regulation and where the motor operates in one direction or is infrequently reversed.

Conveyors, kilns, machine tools, stokers, feed-water pumps, agers, dye jigs, padders, splashers, and washers are typical applications where this particular drive can be used advantageously.

The simplicity of this drive is illustrated by the schematic diagram shown in Fig. 16-47. The only control equipment required consists of an a-c Linestarter, a start-stop push button, and a speed-adjusting rheostat.

To start the drive it is necessary only to operate the START push button which energizes coil *M* of the line contactor. Energization of coil *M* closes the *M* contacts and starts the a-c to d-c motor-generator set. As the series generator is accelerated up to its rated speed, the d-c-series drive motor also starts to rotate. This method of starting acts as a magnetic cushion and prevents shock on the driven load during the acceleration period.

D-C series wound drive motor

FIG. 16-46. Typical series adjustable-speed drive with speed variation by generator-field control.

The speed of the d-c driving motor can be varied by changing the setting of the generator-field rheostat. When all the resistance in the rheostat is effective, the generator voltage and motor speed are at their maximum value. As the rheostat resistance in parallel with the generator field is reduced, the voltage is decreased, and the motor operates at a lower speed.

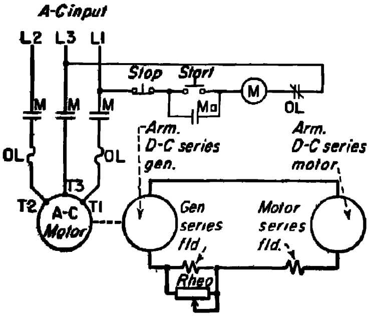

FIG. 16-47. Circuit diagram of adjustable-speed drive.

Once the rheostat has been set for the desired speed, the drive can be started and stopped without touching the rheostat. The driving motor will accelerate to the selected and desired speed after the START push button has been operated. This drive provides constant-torque drive characteristics. Regenerative braking is not possible with this type of drive.

Shunt-wound d-c motors have an inherent speed-increase characteristic of 10 per cent or more as the shunt field heats up. With the series motor used in this type of drive, there is practically no change in speed from cold to hot operation.

The generator rheostat is the chief factor limiting the size of series drive that can be manufactured economically. As the rheostat is in parallel with the generator field and must shunt up to 95 per cent of the full-load current at low operating speeds, the rheostat must consequently have a low resistance and should be mounted reasonably close to the motor-generator set.

A family of typical speed–torque curves taken from actual test data is shown in Fig. 16-48. The top curve is the speed–torque characteristic obtained when the generator is operating at full-field excitation. This set of curves was obtained by gradually shunting the generator-field current. It should be noted that the low-speed curves are practically flat except for a rather abrupt increase in speed for very light loads.

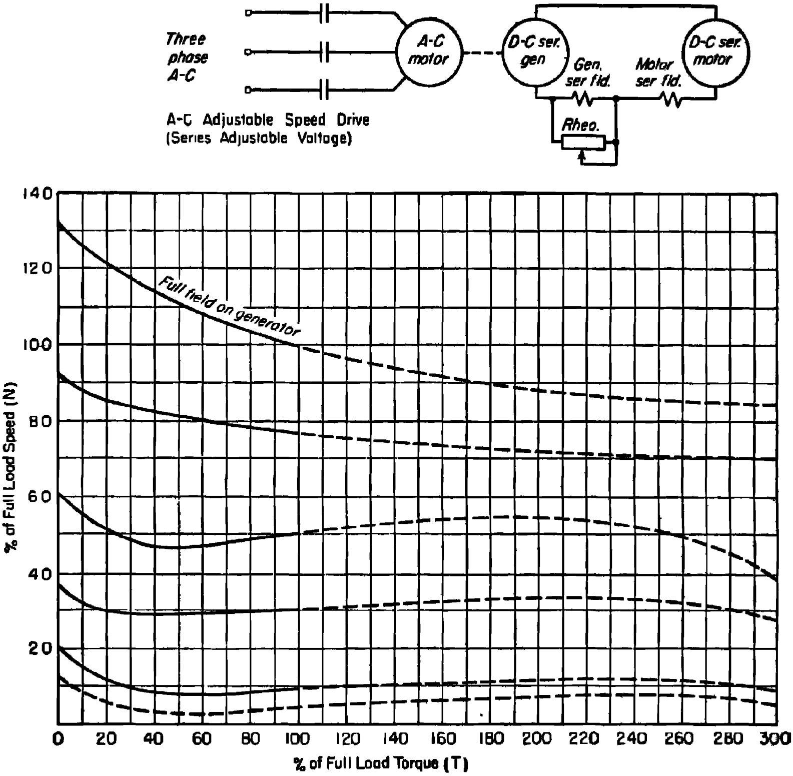

Fig. 16-48. Typical speed–torque curves for speed adjustment of a series-drive motor by series generator-field control.

The speed regulation of this drive based upon the indicated full-load and no-load speeds is rather high. However, for all practical purposes, on most applications the speed regulation is good because there is generally sufficient friction in the driven load so that the increase in speed at very light loads is never actually obtained.

When the rheostat is set for 10 per cent of the full-load base speed, the drive motor can exert a starting torque of five or six times the full-load torque value. Also, the drive can actually be operated at 5 per cent of the base speed as shown by the bottom and dotted curve for short periods for threading or inching operations. Continuous operation at the extremely low speed will cause an excessive temperature rise in the motor because of the decreased ventilation.

D-c Self-excited Shunt Adjustable-voltage Drives.

SPEED RANGE:
12:1 (67 per cent speed reduction by armature-voltage control and 4:1 speed increase by field control)
SPEED DECREASE FROM NO LOAD TO FULL LOAD:
Approximately 20 per cent at low speed
Approximately 10 per cent at base speed
Approximately 25 per cent at high speed
HORSEPOWER:
Up to 15

The self-excited shunt adjustable-voltage drive is another simplified form of the adjustable-voltage group of drives. This type of drive requires a generator that will provide stable operation at reduced voltage while operating self-excited. A stable generator is one that will repeat and hold its output voltage within a reasonable degree of accuracy. An ordinary self-excited generator controlled with a standard rheostat is stable down to approximately 60 per cent of rated voltage at no-load and allows operation over a voltage range slightly less than 2:1.

FIG. 16-49. Typical d-c self-excited shunt adjustable-speed drive with speed variation by armature-voltage and field control.

The generator for a self-excited drive is generally designed to have field saturation at a relatively lower voltage than a standard generator. With this special characteristic, stable operation can be obtained over a voltage range of at least 3:1.

The d-c shunt drive motor differs from a standard motor in that the shunt field must provide full excitation with only one-third the rated output voltage of the generator on the motor field. This is necessary if the speed range of the system is to be 3:1.

Figure 16-49 shows the apparatus required for a typical self-excited shunt adjustable-voltage drive.

The schematic diagram for a typical self-excited shunt drive is shown in Fig. 16-50.

A self-excited shunt generator does not build up its voltage very quickly; therefore, the motor-generator set is usually started without any load. Also, it should be allowed to run continuously, and the d-c drive motor should be started and stopped by the contactor *L* in the d-c circuit. A field relay *FA* ensures that, when the line contactor *L* is open, the motor has full field, and the generator has minimum field, which provides about one-third the rated voltage. When the line contactor *L* closes, the field relay operates to increase the generator excitation and to weaken the motor field to accelerate the motor to the speed determined by the rheostat setting. The series coil *FA* on the field-accelerating relay also operates to increase the motor field and to decrease the generator output voltage automatically if the armature current exceeds a preset value. This field-acceleration relay is sometimes known as a fluttering relay as its contacts close or open continuously during the acceleration period.

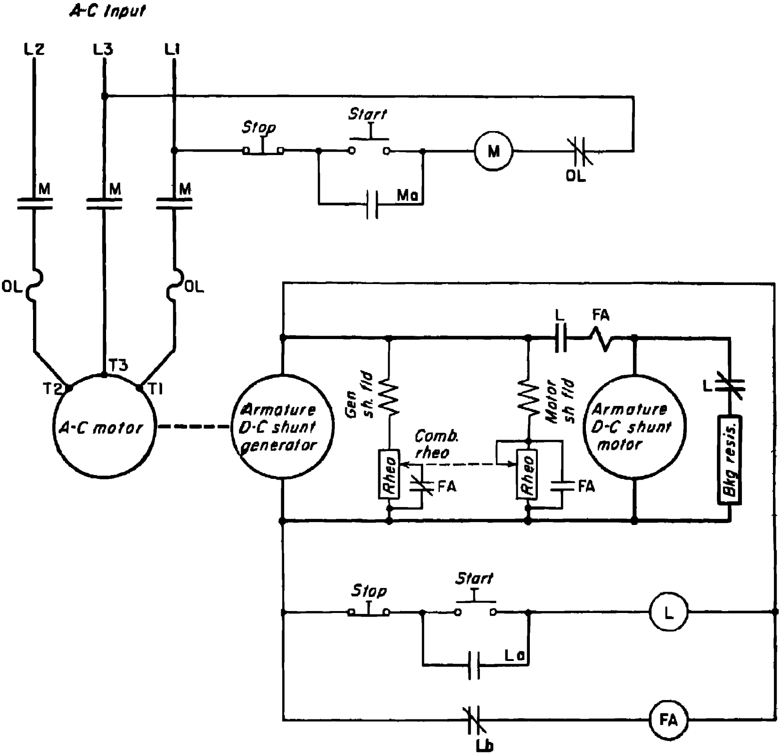

Fig. 16-50. Schematic diagram for a self-excited shunt adjustable-speed drive.

Figure 16-50 also shows how dynamic braking can be provided to stop the drive motor in a minimum of time. The braking resistor is connected across the drive-motor armature by a normally closed contact on the *L* contactor. As the motor field is continuously energized, the motor will operate as a generator when it is paralleled with a resistor. The kinetic energy of the armature is dissipated in the form of heat in the braking resistor.

This type of drive provides a speed range of approximately 12:1. Typical speed-torque curves are shown in Fig. 16-51.

The speed control of this drive is obtained with a combination rheostat which has a resistance section in each field circuit. The sliders on the two rheostats are mechanically connected so that, as one circuit is increased in resistance, the resistance in the other field circuit is decreased. In the rheostat low-speed position, the motor is operated at full field, and the generator is operated at minimum field for a low output voltage. As resistance is cut out of the generator field to raise the voltage, the resistance in series with the motor field is increased at such a rate as to maintain the full-field motor current value. After the rheostat handle has been rotated approximately 180 deg to the full-field generator position, further rotation of the rheostat handle only weakens the motor field to obtain additional speed adjustment by field control. Rated voltage output is maintained from the generator while the motor-field excitation is reduced. This particular drive is more flexible than the series type, as dynamic braking, reversing, inching, and slowdown operations can be obtained relatively easily.

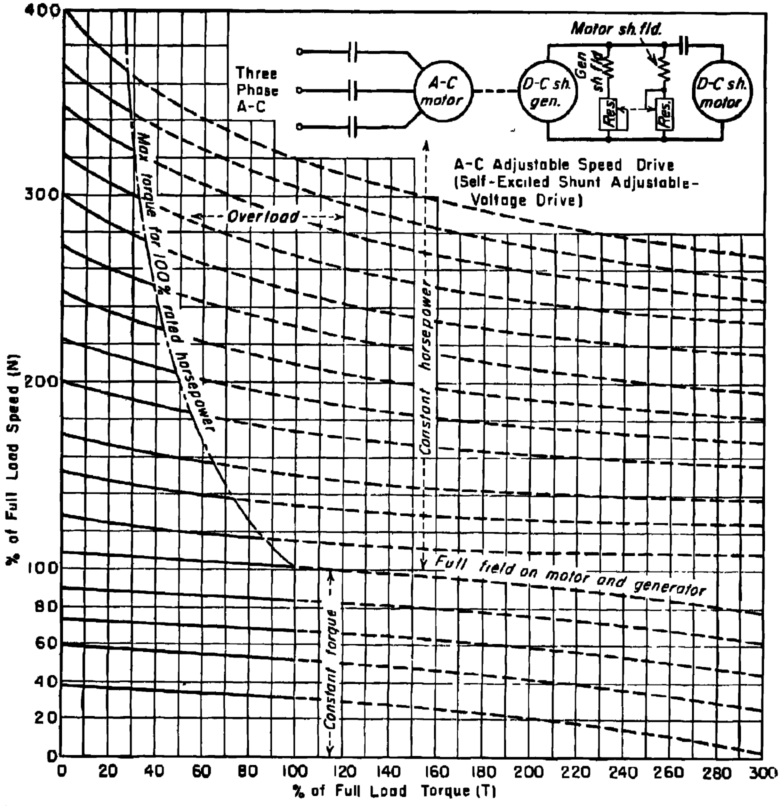

Fig. 16-51. Typical speed-torque curves for speed adjustment of a self-excited shunt drive by armature-voltage and field control.

D-c Separately Excited Shunt Adjustable-voltage Drive.

Speed Range:

40:1 (90 per cent speed reduction by armature-voltage control and 4:1 speed increase by field control)

Speed Decrease from No Load to Full Load:

Approximately 50 per cent at low speed

Approximately 10 per cent at base speed
Approximately 25 per cent at high speed
Horsepower:
Unlimited

The conventional adjustable-voltage drive, which is also known as the Ward-Leonard system, is more expensive than the series drive previously described. However, the increased cost is justified for many applications as the speed range is four times greater than that for the other drive.

This conventional adjustable-voltage drive was originally developed and used for large machines of several hundred to several thousand horsepower where it was impractical to close or open the main armature circuits. Also, for some large steel-mill applications, this method of motor starting and speed control must be used as contactors are not available with the current rating sufficient to handle the motor-armature current.

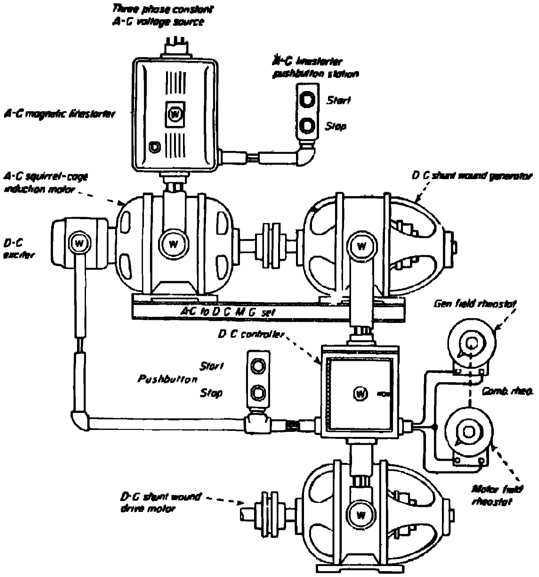

Fig. 16-52. Conventional d-c adjustable-voltage drive with speed variation by armature-voltage and field control.

The apparatus required for a typical adjustable-voltage drive is illustrated in Fig. 16-52. It should be noted that the equipment required is similar to that for a self-excited shunt drive with the exception of the addition of an exciter. Exciters are designed to provide excitation voltages which are considerably lower than those which can be obtained from self-excited generators.

The circuit diagram for a moderately rated adjustable-voltage drive is shown in Fig. 16-53. The motor generator set a-c drive motor is started by operating the START push button to close the *M* contactor. For some applications it is convenient to control the starting and stopping of the d-c drive motor by means of the *L* contactor in the d-c circuit. A field-accelerating relay is generally used to control the motor acceleration when the speed range obtained by field weakening is greater than 2:1.

For applications where the drive motor is relatively large, the line contactor *L* is omitted, and the generator- and motor-field rheostats are electrically connected to the controller in such a manner that the generator must be operating at a low voltage before the motor can be started. The speed of the motor can then be readily adjusted, first with the generator-field rheostat and then with the motor-field rheostat. These rheostats are often motor operated for remote or automatic operation.

When it is necessary to reverse the direction of the d-c motor, the control can be readily arranged to reverse the generator field. The contactors required for reversing the generator-field connections are usually available control devices and relatively very small compared to the switching equipment that would be required to reverse the motor-armature circuit. Reversal of the generator field will reverse the polarity of the generated voltage. This in turn will cause reversal of the drive motor as the direction of the motor field is not changed.

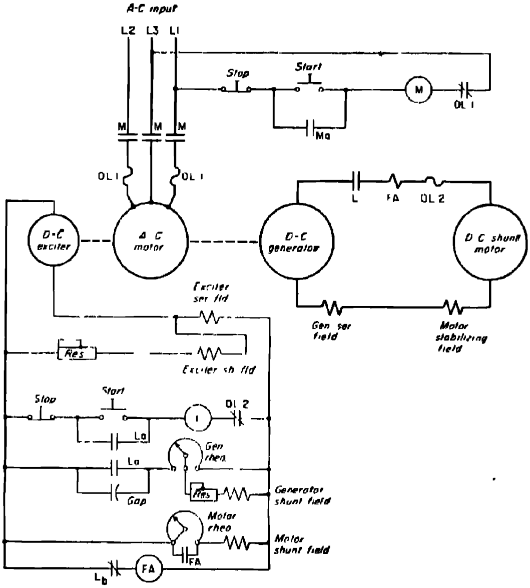

FIG. 16-53. Diagram for a typical conventional adjustable-voltage drive.

Figure 16-54 shows typical speed–torque curves for the separately excited adjustable-voltage drive. This drive provides constant torque below the base speed and constant horsepower above the base speed.

For adjustable-voltage drives the power losses, which make speed adjustment by armature-circuit resistance in constant-voltage drives inefficient, are eliminated. Also, the absence of additional resistance in the armature circuit improves the regulation.

Field rheostats can be readily built with a large number of steps and will make it possible to start and stop a motor smoothly. This is absolutely essential for high-speed elevators and papermaking machines.

The adjustable-voltage system also provides a means for controlling a group of motors simultaneously. Steel-mill roll-out tables are sometimes controlled in this manner.

D-c Separately Excited Shunt Adjustable-voltage Drives with Rototrol Regulators.

SPEED RANGE:

120:1 (approximately 98 per cent speed reduction by armature-voltage control and 2:1 speed increase by field control)

Speed Variation from No Load to Full Load:
±3 per cent
Horsepower:
Unlimited

The addition of a Rototrol regulator to a conventional adjustable-voltage drive provides a drive with a greater speed range than any of the other types of drives now commercially available.

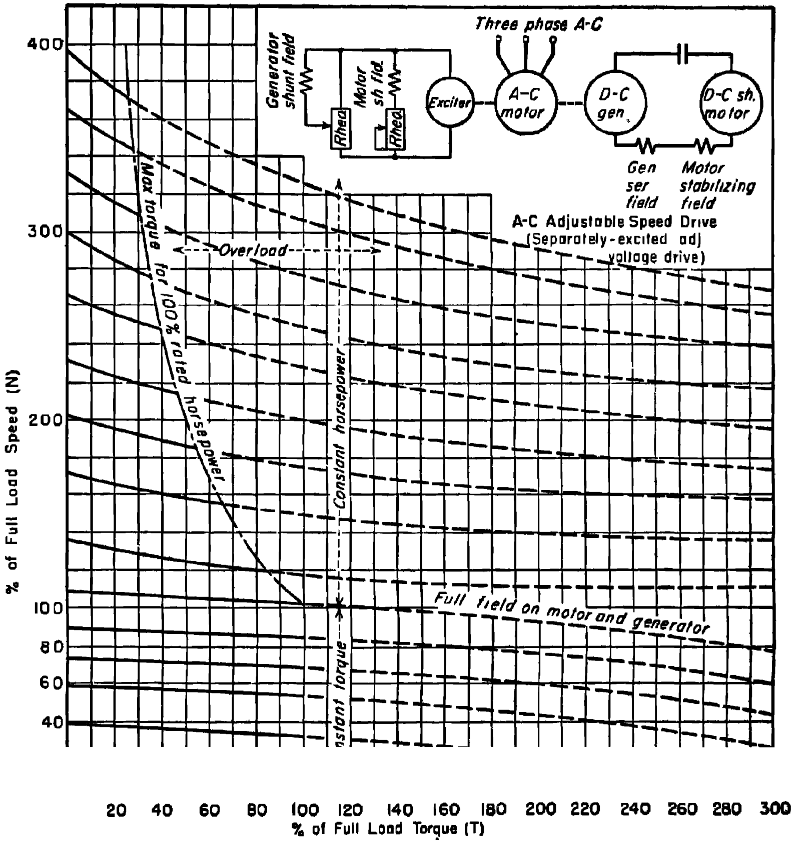

Fig. 16-54. Typical speed–torque curves for a conventional adjustable-voltage drive.

In order to have a drive that operates with a speed characteristic which does not change appreciably from no load to full load, compensation must be made for certain inherent generator and motor characteristics that normally cause poor regulation.

The residual voltage of a commercially built generator and the motor-armature *IR* drop are the chief factors that prevent low speeds and good regulation. A Rototrol, which is a small d-c generator with special field windings, can be added to the conventional drive to compensate for these factors.

A typical adjustable-voltage drive with a Rototrol regulator unit is shown by Fig. 16-55. The unit assembly of the motor-generator set a-c drive motor, the d-c shunt-wound generator, the d-c exciter, and the Rototrol unit makes a very compact unit which facilitates the installation.

The residual voltage of a typical d-c generator is between 3 and 4 per cent of the normal operating voltage. For this reason, a d-c motor that is energized from such a generator is limited to a speed range of about 25:1 for an adjustable-voltage control system. The residual field of the generator prevents the output voltage from being any lower even though the generator-field windings are not even excited. As the magnitude of the residual field is a function of the previous magnetic history of the generator, it is also necessary that the control device or means used to compensate for and overcome the residual voltage be able to measure the actual residual voltage accurately.

Fig. 16-55. D-c adjustable-voltage drive with compensation for the generator residual voltage and the motor-armature *IR* drop.

Because of the motor-armature *IR* drop, the speed of a d-c motor decreases as the load current increases. In order to obtain a flat speed-torque characteristic, a speed-regulating means must always automatically increase or decrease the generator output voltage which is applied to the motor by an amount exactly equal to the change in the motor *IR* drop for all conditions of load. A Rototrol can compensate for the motor-armature *IR* drop and has been very effectively used for this purpose.

The basic circuit of an adjustable-voltage drive with a Rototrol for constant speed regulation is illustrated in Fig. 16-56. A manually operated autotransformer type of starter for the motor-generator set a-c drive motor has been shown as this type of starter is frequently used to start a-c motors where the line disturbances must be kept to a minimum. When lower than rated voltage is applied to an a-c motor, the starting current and resultant torque are decreased as previously described for a-c induction motors.

In general, Rototrol generators are designed for operation on the straight or air-gap portion of their saturation curves. The voltage that they generate will be directly proportional to the net field excitation. The Rototrol unit is usually directly connected to the motor-generator set and is driven at a constant speed.

The main generator-field winding is divided in two equal sections and is connected in a special bridge circuit. The resistances of the main generator- and Rototrol-field sections are balanced with resistor units in the other two sides of the bridge so that, with zero voltage from the Rototrol armature, there is no difference in potential between the points to which the Rototrol armature is connected. The main generator-field sections are accumulative, and the desired speed of the motor is controlled by the generator-field rheostat in the usual manner. The resistance in series with the Rototrol armature is used to tune the circuit so that the Rototrol operates on the air-gap portion of the saturation curve.

At no-load on the motor, resistor $R6$ is adjusted so that the fields produced by $RF1$ and $RF2$ are completely neutralized by the shunt pilot field $RF3$. (Magnetic fields $RF1 + RF2 - RF3 = 0$.) Under these conditions the generated output voltage of the Rototrol armature is zero as the net magnetic field is zero.

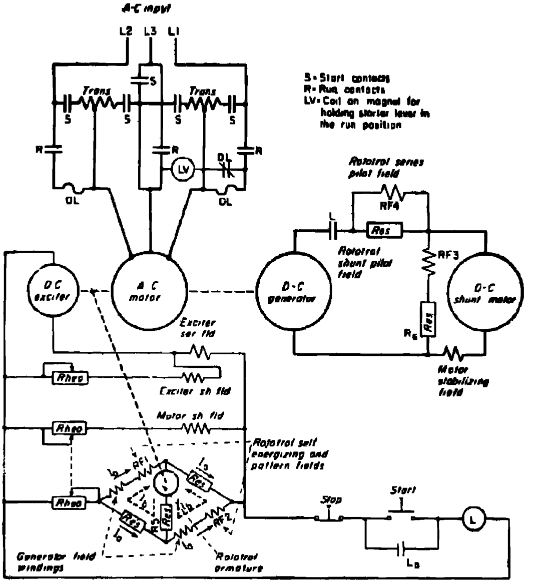

FIG. 16-56. Diagram for an adjustable-voltage drive with automatic speed regulation by means of a Rototrol.

The Rototrol shunt $RF3$ and series $RF4$ pilot fields are proportioned so that, for any load conditions, the net ampere-turns are proportional to the counter emf of the d-c drive motor. The speed of a d-c motor with constant field excitation is proportional to its counter emf which, in turn, is equal to the applied voltage minus the motor-armature IR drop.

As an increase in the motor load results in an increase in the motor-armature current, the ampere-turns of the Rototrol series pilot field $RF4$ also increase. The ampere-turns of the series field $RF4$ add to those of the self-energizing fields $RF1$ and $RF2$. Furthermore, a decrease in the main generator output voltage because of the regulation also decreases the ampere-turns produced in the Rototrol shunt pilot field $RF3$. As a result of these changes in the net field excitation, the Rototrol now generates a voltage which circulates the current I_b through the Rototrol self-energizing and pattern fields and the main generator fields to supplement the excitation normally produced by the current I_a from the exciter bus. This additional main generator-field excitation increases the generator output voltage to a value that is sufficient to restore the d-c drive-motor speed to the desired and preset value.

The Rototrol series field *RF*4 also compensates the circuit for the resistance drop in the lines and motor armature. The shunt pilot field *RF*3 compensates the circuit for the resistance drop as well as the magnetizing effects that occur in the main generator armature. All these conditions are integrated by the Rototrol, and the resultant compensation produces a flat speed–torque characteristic.

It should be noted that the d-c exciter supplies the normal generator-field excitation and that the Rototrol supplies only the regulation excitation necessary to maintain the motor speed at a substantially constant value.

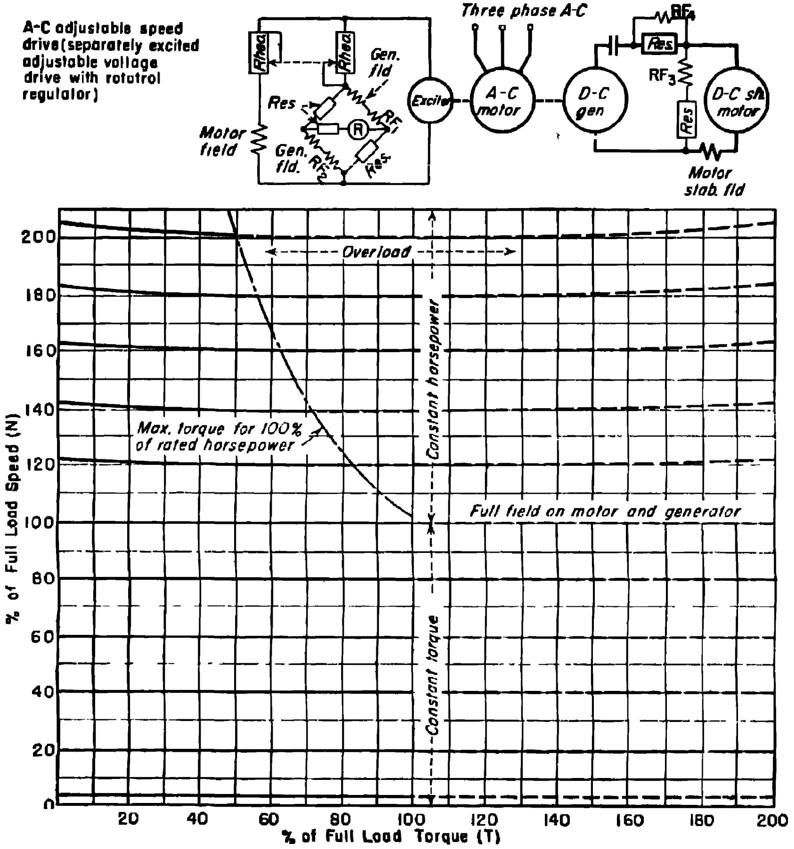

FIG. 16-57. Typical speed–torque curves of an adjustable-voltage drive with a Rototrol unit for 120:1 speed range.

Figure 16-57 shows typical speed–torque curves taken from actual test data and illustrates the speed control that can be obtained from this type of drive. The motor has no tendency to stall even at speeds of one-sixtieth of the base speed. At light loads for this very low speed, the voltage required by the drive motor is less than the residual voltage of the main generator. The Rototrol reverses the current in the field of the generator to buck the residual voltage to a value that gives the required motor speed. As the motor load increases, the Rototrol voltage polarity is restored to the original condition in order to build up the generator voltage to compensate for the motor *IR* drop.

The use of a Rototrol unit in an otherwise conventional adjustable-voltage drive gives a speed range far greater than the supposed limits of a few years ago without greatly complicating the electrical apparatus or circuit. These wide speed ranges were formerly obtainable only with laboratory apparatus.

The particular drive illustrated has a combination main generator- and motor-field rheostat so that full field is continually maintained on the motor when it is operating below the base speed. This drive provides constant torque below the base speed and constant horsepower above the base speed.

Other basic circuits have been developed so that a Rototrol unit can be applied to a drive to provide more accurate regulation and control for a specific speed, to maintain constant-torque output, to maintain constant-horsepower output, to give smooth acceleration and deceleration, or for any other drive characteristic that can be measured in units of voltage or current.

This type of drive is ideal for automatic welding heads, elevators, metal planers, core-type paper reels, paper machines, skip hoists, electric shovels, machine tools, etc.

D-c Electronic (Mot-o-trol) Adjustable-voltage Drives.

Speed Range:
40:1 (approximately 95 per cent speed reduction by armature-voltage control and 2:1 speed increase by field control)
Speed Decrease from No Load to Full Load:
Approximately 10 per cent at low speed
Approximately 1½ per cent at base speed
Approximately 8 per cent at high speed
Horsepower:
Up to 15

An electronic power supply can be used in place of the motor-generator set in a conventional adjustable-voltage drive. This is especially advantageous, particularly in the smaller drive ratings, where the customary additional rotating and relatively large control equipment may not be suitable for a particular installation.

The Mot-o-trol electronic drive provides a wide and stable speed range, good speed regulation, and a very smooth and automatic acceleration of the d-c drive motor.

The heart of the Mot-o-trol is the electronic power supply for the armature and field of the d-c motor. Grid-controlled thyratron tubes are used in the rectifiers which convert either a single-phase or polyphase a-c power source, depending upon the rating, to a d-c voltage supply.

The control characteristic of a typical thyratron tube is shown in Fig. 16-58. The positive anode voltage at which a thyratron tube will conduct current can be controlled by a very small potential on the grid with respect to the cathode.

As shown in the right-hand figure, a tube can be prevented from firing when a positive half cycle of voltage with a rms value of 440 (or a peak of 620) volts is impressed between the anode and cathode if the control grid is energized with a negative potential of more than 4 volts.

A thyratron type of tube will conduct current only when the anode is at a positive potential with respect to the cathode, and once the mercury vapor in the tube ionizes, the conduction can be stopped only when the anode-to-cathode voltage decreases to a very low value.

In the Mot-o-trol electronic drive, an adjustable voltage for the d-c motor armature is obtained by advancing or delaying the point on the a-c anode-voltage wave at which the thyratron tube conducts current.

Figure 16-59 shows the control means and principle which are used to vary the rectifier output voltage from zero to the rated value. A small transformer with a center tap, a resistor, and a capacitor form a phase-shifting circuit. This circuit is adjusted for many applications so that the voltage E_g lags the anode voltage E_A by approximately 90 deg. By connecting a d-c voltage E_b source which is adjustable from a suitable negative to a positive value in series with the a-c grid voltage E_g, the a-c grid voltage can be shifted vertically up and down with respect to the zero axis of the anode voltage E_A. As shown by the three voltage-relationship diagrams, the tube-firing or conduction time can be accurately controlled for a conduction period of zero to a maximum time of ½ cycle merely by varying the d-c grid-voltage component from a negative to a positive value. This type of control is used for controlling both the armature- and shunt-field voltages.

The apparatus required for a typical nonreversing electronic drive is shown by Fig. 16-60. A complete Mot-o-trol electronic drive is usually comprised of an a-c power transformer, an electronic controller, an operator's control station, and a d-c shunt motor.

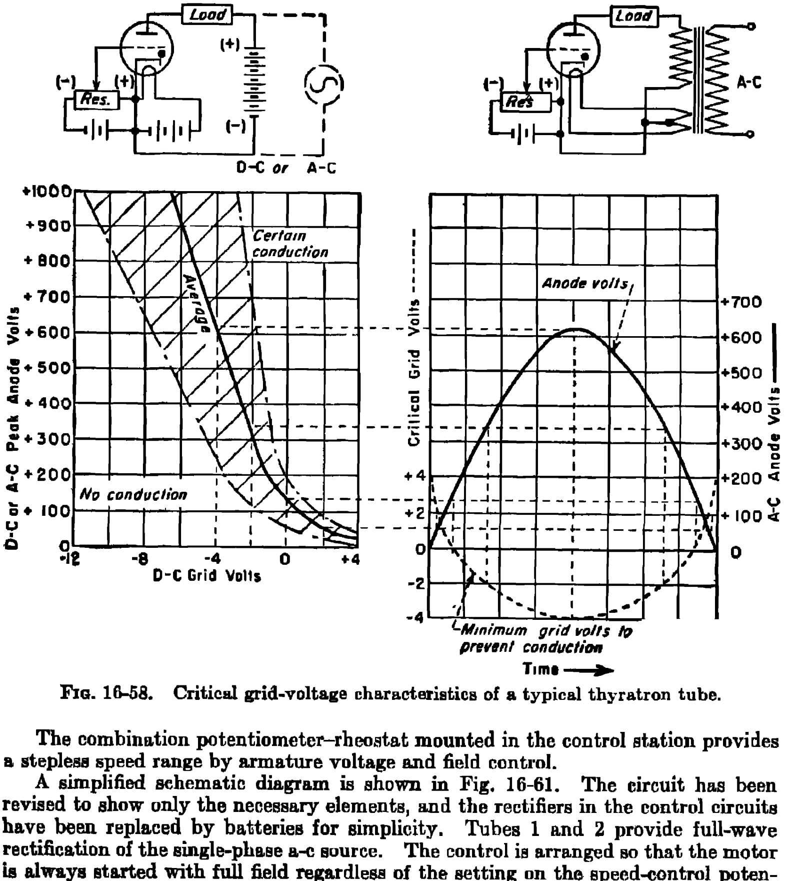

Fig. 16-58. Critical grid-voltage characteristics of a typical thyratron tube.

The combination potentiometer–rheostat mounted in the control station provides a stepless speed range by armature voltage and field control.

A simplified schematic diagram is shown in Fig. 16-61. The circuit has been revised to show only the necessary elements, and the rectifiers in the control circuits have been replaced by batteries for simplicity. Tubes 1 and 2 provide full-wave rectification of the single-phase a-c source. The control is arranged so that the motor is always started with full field regardless of the setting on the speed-control potentiometers *P*2 and *P*2*A*. The field-weakening control does not become effective until the motor accelerates to its base speed.

Transformer 3 and tubes 5 and 9 provide armature-current limit control. Fast, smooth, and shockless motor acceleration is automatically provided by these devices which control the d-c voltage component of the grid voltage which controls the 1 and 2 thyratron tubes. In this manner, the voltage output of the armature-voltage rectifier tubes is always precisely controlled so that a preset limit on the current is never exceeded.

Tube 6 also automatically controls the grid voltage of tubes 1 and 2 so that the motor *IR* drop is compensated for and does not cause the motor speed to decrease with an increase in the load.

Tube 7 corrects the inherently poor voltage regulation of tubes 1 and 2. The coordinated operation of all the control elements provides an output voltage from the rectifier that will give a flat speed-torque characteristic.

The shunt-field excitation current is rectified by tube 3 which is manually controlled by the potentiometer *P2A* and is automatically controlled by the voltage-regulation-tube network. Tube 4 provides a discharge circuit for the field current during the time that tube 3 is not conducting.

FIG. 16-61. Simplified schematic diagram of a typical Mot-o-trol electronic drive.

Typical speed-torque curves are shown in Fig. 16-62. Much development has been and is being done on improving the operation and increasing the horsepower range of electronic motor controls.

The d-c motors used in this type of drive are usually furnished with a somewhat larger than standard frame than that required for motors operating at constant speed and from nonpulsating d-c power sources. This is necessary as the pulsating d-c current from the rectifier circuit causes more heating in the motor than results from operation on steady direct current. Also, at low speeds, the ventilation of the motor is materially reduced. An electronically controlled drive of this type generally provides the most satisfactory operation when one manufacturer supplies the complete equipment.

This type of drive can be readily supplied suitable for inching and reversing service and dynamic braking. It is not suitable for regenerative braking. The Mot-o-trol is particularly well suited for machine-tools, conveyors, key seaters, gear-cutting machines, and any other applications where a well-regulated and wide speed range is desired. With the exception of the actual drive motor, the electrical apparatus is also vibrationless and provides a more compact unit than an equally rated motor-generator set and its control.

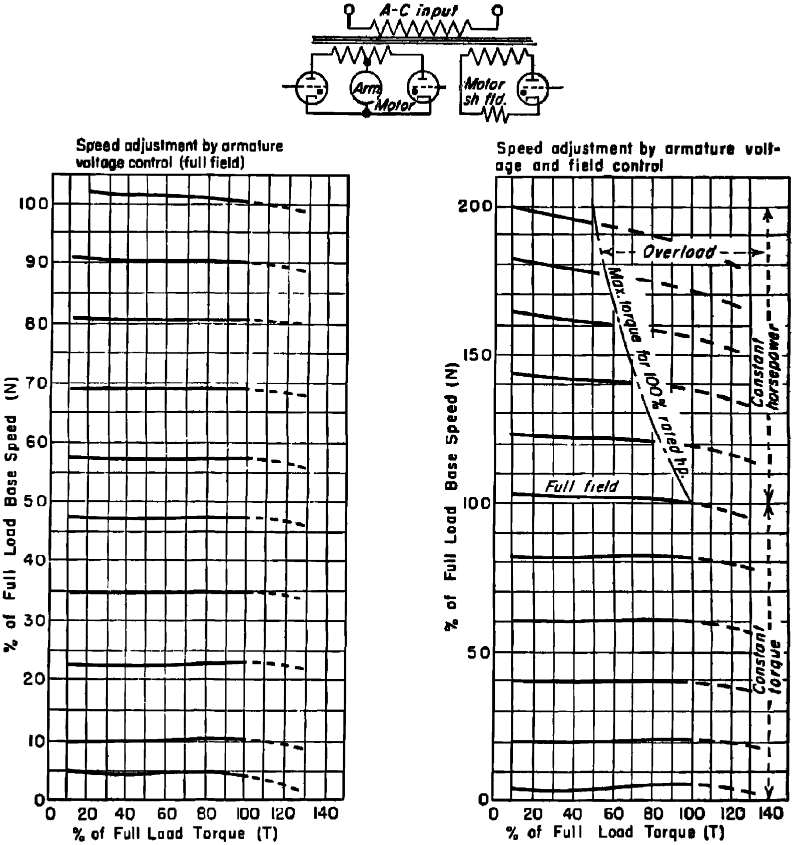

FIG. 16-62. Typical speed–torque curves for a d-c shunt motor operated from an adjustable-voltage electronic power source.

A-C MOTOR DRIVES—A-C POWER SOURCE AND CONVERSION EQUIPMENT

The speed of an a-c motor can be adjusted by changing the frequency of the applied voltage. Refer to Figs. 16-24, 16-25, and 16-26 for curves and a table of motor speeds vs. frequencies. The main disadvantage to this type of speed control is that the adjustable-frequency system generally requires considerable conversion equipment.

A-c Adjustable-frequency Drives—Motor-generator Sets.

SPEED RANGE:
  5 or 6 : 1 for typical drives (80 or 84 per cent speed reduction by frequency control)
SPEED DECREASE FROM NO LOAD TO FULL LOAD:
  Without d-c to a-c motor-generator set drive-motor compensation
    Approximately 80 per cent at low speed
    Approximately 15 per cent at base speed
  With d-c to a-c motor-generator set drive-motor compensation
    Approximately 50 per cent at low speed
    Approximately 5 per cent at base speed
HORSEPOWER:
  Unlimited

A typical adjustable-frequency system is illustrated in Fig. 16-63. It consists of an a-c synchronous drive motor and a d-c shunt-wound generator for the a-c to d-c adjustable-voltage d-c motor-generator set, a d-c drive motor and an a-c generator for the d-c to a-c adjustable-voltage and -frequency motor-generator set, and an a-c squirrel-cage drive motor.

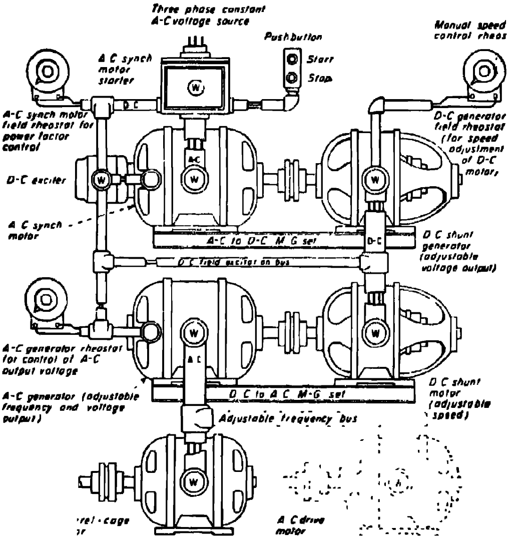

FIG. 16-63. Typical adjustable-frequency drive with speed adjustment by frequency control.

It should be very obvious that such a drive is practical and economical only when a number of drive motors are to be simultaneously controlled and operated at exactly the same speed. Such a drive is not feasible for a single drive motor as the ultimate speed range could be obtained much better from the d-c motor which drives the a-c generator. This type of drive has often been used for steel-mill roll-out-table drives.

An undesirable characteristic of this drive is the fact that the speed regulation of the actual drive motor is affected by the summation of the per cent regulation of all the machines in the system. This poor regulation characteristic can be minimized and reduced to almost that of the squirrel-cage drive motor by using a synchronous drive motor in the a-c to d-c motor-generator set and by employing a Rototrol regulator to maintain the speed of the d-c drive motor of the d-c to a-c motor-generator set at a reasonably constant value.

When a synchronous motor is used for the driving means in the a-c to d-c motor-generator set, power-factor correction can be obtained in addition to driving the set at an absolutely constant speed.

The schematic diagram of a typical adjustable-voltage drive is shown by Fig. 16-64. To put the a-c drive motor in operation, the START push button is operated to start the synchronous motor. When the START button completes a circuit to and energizes the coils M and T, the M contacts close and apply voltage to the synchronous motor. The usual type of synchronous motor has damper bars in the rotor and starts similarly to a squirrel-cage induction motor. During the starting period, the synchronous-motor d-c field winding is shunted by a resistor which is in series with a normally closed contact F. The diagram symbol T represents a time-delay relay which operates to close the T contact after a definite time period. After the synchronous motor accelerates to a speed high enough for synchronization, the relay contact T closes and energizes the coil F of the field contactor. This opens the shunting-resistor circuit and applies direct current to the field. The synchronous motor should now pull into step and run at an absolutely constant speed. The synchronous-motor field is shunted to prevent high voltage from being induced in the winding during the starting and stopping periods.

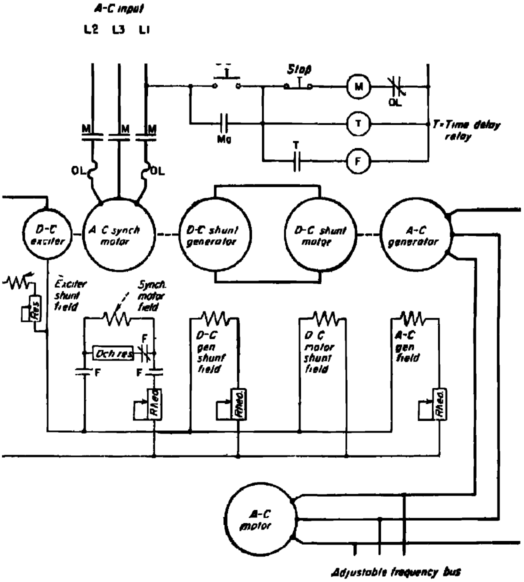

FIG. 16-64. Circuit diagram for a typical a-c adjustable-speed drive with speed variation by frequency control.

The control can be arranged so that the actual drive motors are always started at the lowest speed. This speed control and adjustment can be readily obtained by operating only the d-c generator shunt-field rheostat.

Typical speed-torque curves for a three-phase squirrel-cage drive motor are shown in Fig. 16-65. These curves were plotted from actual test data on a motor for application to a roll-out table. The motor developed approximately 0.9 hp when operated on 65 cycles for the base speed.

As the inductive reactance of an a-c motor-field winding varies directly with the frequency, the applied voltage and frequency must always be in approximately the same ratio of volts per cycle for any speed. This is essential in order to develop the necessary torque and to limit the current to a safe value. ($X_L = 2\pi fL$, where X_L = the inductive reactance, $\pi = 3.14$, f = the frequency, and L = the inductance of the winding.) The winding-resistance factor is predominant at the lower frequencies.

These curves are based upon the regulation only of the a-c squirrel-cage drive motor. Unless the a-c and d-c motor-generator set drive motors operate at constant speed for any setting, the actual regulation of the drive will be greater than that indicated. Any intermediate speeds between those indicated can be readily obtained.

With this type of control, a load can be started smoothly as the starting torque steadily increases as the applied voltage and frequency to the drive motor are increased.

When it is necessary that the drive motors operate at an absolutely constant speed, synchronous motors can be used. Also, nonexcited synchronous motors for lower ratings can be operated very satisfactorily from the adjustable-frequency set. Nonexcited synchronous motors with fractional-horsepower ratings have been applied to drive nylon-spinning buckets where an absolutely constant operating speed is desired with adjustability in a range of approximately 6:1.

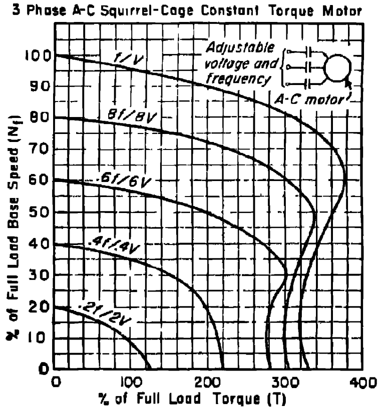

Fig. 16-65. Typical speed-torque curves for a three-phase squirrel-cage motor operated from an adjustable-frequency system.

A-c Adjustable-frequency Drives—Induction-generator Sets.

Speed Range:
  2:1 or 3:1 for typical drives (2:1 or 3:1 speed increase by frequency control)
Speed Decrease from No Load to Full Load:
  With induction motor driven set and induction drive motor
    Approximately 10 per cent at base speed
    Approximately 3 per cent at high speed
  With synchronous motor driven set and induction drive motor
    Approximately 5 per cent at base speed
    Approximately 1½ per cent at high speed
  With synchronous motor driven set and synchronous drive motor
    0.0 per cent at base and high speed
Horsepower:
  Up to 60 (for induction motor driven sets)
  Up to 100 (for synchronous motor driven sets)

Induction frequency changers are used extensively for supplying power to high-frequency drive motors in the wood-working and rayon industries where relatively high speeds are required. The induction type of generator is ideal for applications where sturdiness, simplicity, reliability, low maintenance, and good regulation are important. Commercial sets are available for converting from 25-, 50- and 60-cycle frequencies up to 175 or 180 cycles. Induction generators are not used to obtain lower than supply frequencies as the lower than base speeds can be readily obtained with multispeed motors.

An induction generator is actually a wound-rotor induction motor whose rotor is driven opposite to the direction of its rotating magnetic field.

When an induction-motor primary field is energized with a polyphase voltage, a rotating magnetic field is produced. The speed of the field rotation depends upon the frequency and the number of poles. This primary-circuit revolving field induces a voltage in the rotor or secondary winding of the motor similar to the action that occurs in a two-winding transformer. The basic circuit diagram for and the relative directions of rotation for the primary winding field and the rotor for an induction frequency-changer set are shown by Fig. 16-66.

*Note - Speed N1 depends on freq f1 and number of poles

Fig. 16-66. Basic circuit diagram for an induction-frequency changer.

If the rotor is held stationary, the output frequency will be the same as the input frequency.

To secure a frequency higher than that of the power supply, the rotor must be driven by external means in a direction opposite to that of the rotating field. The relationship between the output and input frequencies is given in the equation at the bottom of Fig. 16-66.

A portion of the power output from an induction generator is supplied by direct transformer action between the primary winding and the rotor winding. This power transfer varies with the ratio of input to output frequency. For example, on 60- to 180-cycle conversion, one-third of the power output is supplied by direct transformer action. The set drive motor must be large enough to supply the other two-thirds of the output plus a portion of the induction-generator losses.

A typical three-speed drive is illustrated by Fig. 16-67. A motor-generator set can be readily constructed from standard machines. With an induction motor and two wound-rotor motors with a different number of poles, two frequencies higher than that of the line supply can be obtained. A standard a-c Linestarter with additional overload protection for the induction generators can be used for primary control.

For the secondary control, an a-c controller and a selector switch can be used to operate the drive motor at the desired speed.

The schematic diagram for the three-speed drive is illustrated by Fig. 16-68. The induction-generator set can be put in operation by depressing the START button. This will start the motor-generator drive motor and energize the primary windings of the induction generators.

The manually operated cam selector switch can be set for the desired speed. This particular control scheme provides low-voltage protection. The slow *S*, medium *M*, and fast *F* speed contactors are interlocked electrically by electrical interlocks to prevent the coil on a contactor from being energized unless the other two contactors are fully open.

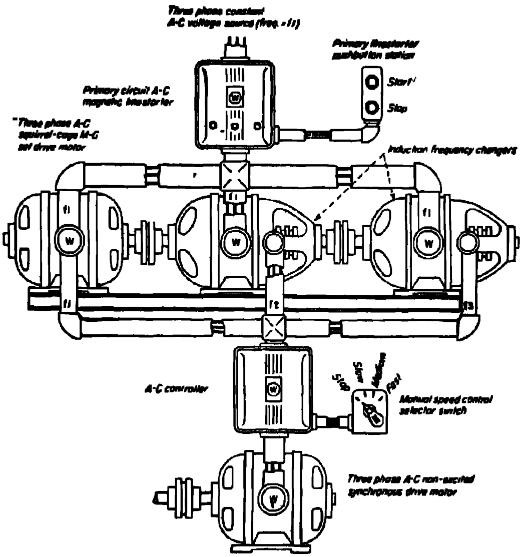

Fig. 16-67. Typical three-speed drive with speed adjustment by frequency control. Induction generator set for higher-than-line frequencies.

The squirrel-cage type of induction motor is frequently operated on the power output of an induction-generator set. However, to illustrate how an absolutely constant output speed can be obtained, the speed–torque characteristics of a nonexcited synchronous motor are shown in Fig. 16-69. These curves are based upon a power supply with 0 per cent regulation. This frequency regulation of 0 per cent can be obtained by using a synchronous motor to drive the induction generators at absolutely constant speed.

A nonexcited synchronous motor is similar to an ordinary squirrel-cage induction motor except for slots that are milled in the armature. This alteration changes the reluctance of and the distribution of the magnetic lines of flux in the armature iron. The flux lines are concentrated in certain armature regions similar to machines with salient poles. The starting torques shown for this type of motor are greater than those for a three-phase squirrel-cage motor of the same full-load rating, as the rated output of a given nonexcited synchronous motor is only about one-third that of the standard rating of the motor from which it was made.

This particular type of drive motor pulls into step at approximately 150 to 225 per cent of full-load torque and then operates at a constant speed. The pull-out torque is higher than the pull-in value and is approximately as shown in Fig. 16-69. The pull-in torques for the 100 and 200 per cent base speeds can be increased to that at 300 per cent speed by slightly increasing the applied voltage.

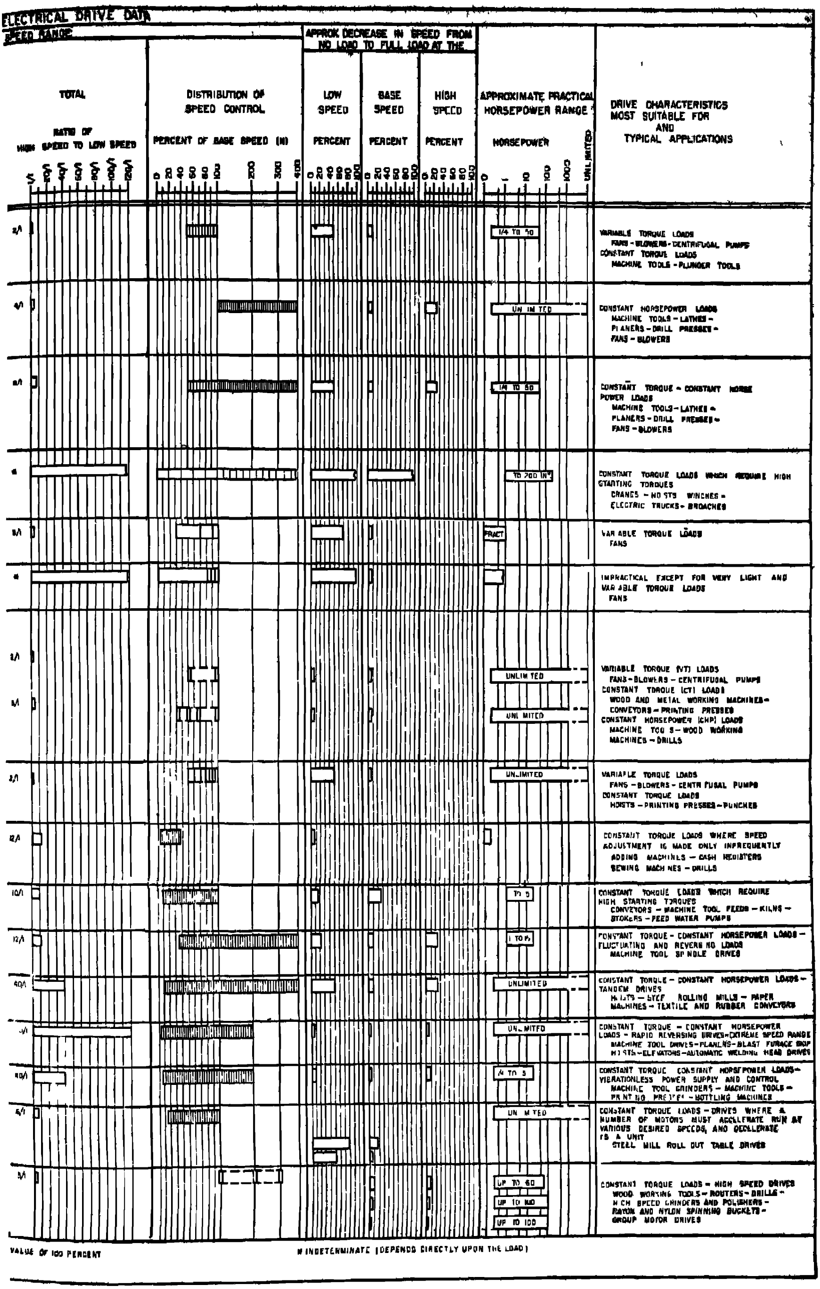
FIG. 16-70. Graphical summary and compari-



son of the adjustable-speed drives available.

For just one or two speeds and where intermediate operating speeds are not required, the induction frequency-changer set is much more economical to use than the adjustable-frequency set which was illustrated in Fig. 16-63.

SUMMARY AND COMPARISON OF ADJUSTABLE-SPEED DRIVE DATA

Figure 16-70 gives a graphical summary and comparison of the adjustable-speed drives that are now available. In selecting the most satisfactory drive for a given application, the cost, speed range, speed in rpm, change in speed from no load to full load, and the size available must all be taken into account.

FLUID DRIVES (HYDRAULIC COUPLINGS)

BY AMERICAN BLOWER CORP., HYDRAULIC COUPLING DIVISION STAFF

Hydraulic couplings, more popularly known as "fluid drives," operate on the hydrokinetic principle, using two vaned rotors to transmit power, one of which is connected to the prime mover and the other to the output shaft (Fig. 17-1).

There are basically two commercial fluid drives available—the constant-filling unit popularized in automobiles and the variable-filling unit widely used with constant-speed electric motors for variable-speed industrial drives. The variable-speed units are manufactured in several types according to the duty, as discussed in this subsection.

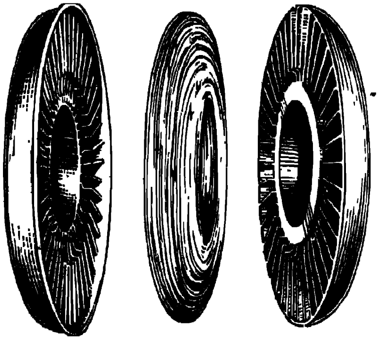

FIG. 17-1. Fluid drive principal parts: (*left to right*) impeller, oil vortex, and runner.

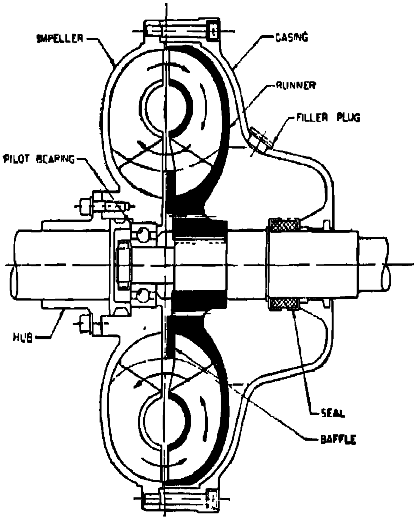

FIG. 17-2. Constant-filling fluid drive.

In the constant-filling design of fluid drive (Fig. 17-2), the rotating elements are initially filled with the proper charge of oil and sealed. The impeller rotates with the motor, and the runner rotates with the output shaft. The casing, which is attached to the impeller, retains the oil and supports the seal at the output shaft.

The uses of this fluid drive are best divided into (1) electric-motor applications and (2) internal-combustion-engine applications. In both cases, fluid drive serves as a flexible cushioned power connection. The ratings and sizes available are given in Tables 17-7 to 17-12, inclusive.

VARIABLE-FILLING–VARIABLE-SPEED DESIGN

Variable-speed fluid drives consist of the basic vaned rotors and a casing with an additional means of adding or removing oil from the vortex and thus varying the torque-transmitting capacity and/or the output speed. The usual means of varying oil filling and consequently speed are discussed below. The lever-controlled design is commonly applied to industrial drives ranging from 1 to 350 hp. The pump-controlled design is commonly applied to industrial drives ranging from 100 to 3,000 hp.

Lever-controlled Fluid Drive. *Principle of Controlling Speed.* The lever-controlled fluid drive is shown by Fig. 17-3. When running, the outer casing acts as a rotating reservoir, storing oil centrifugally against the rim. The movable scoop dips into the rotating reservoir and transfers oil to the working circuit, as required for the desired output speed and/or torque. A continuous circulation of oil takes place. The oil leaves the vortex by calibrated nozzles and circulates through the scoop tube, out of the manifold, through a cooler, and back via the manifold to the working vortex. When the motor is standing still, the outer casing has sufficient capacity to store the oil below the center line and below the labyrinth seal at the manifold.

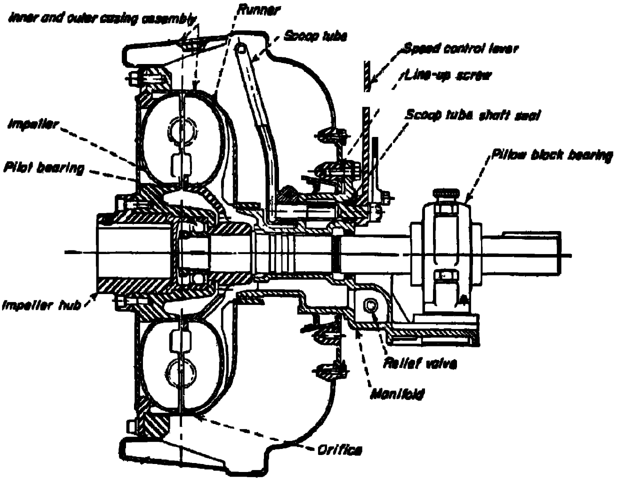

Fig. 17-3. Lever-controlled fluid drive.

The position of the operating lever determines speed. This lever may be manually operated or automatically operated by a diaphragm or piston. It can also be remotely operated by a damper motor and push button.

Arrangements. The arrangements commonly employed are shown by Fig. 17-4. For belt drives the manufacturers recommend the two bearing arrangement on the output shaft.

Applications. Applications and the principal functions of the fluid couplings in each case are listed below. In all cases, constant-speed motors are used.

---

* Strip winders, test stands, and similar special-duty machines may require special consideration.

† Including oil.

‡ The center of gravity is given in inches beyond the end of the motor shaft.

Note: The overhung weight of the fluid drive is carried by the motor shaft. For this reason it is advisable to use standard motors with full-size shaft and bearings to carry this weight.

FANS AND CENTRIFUGAL PUMPS—stepless variable speed, no-load motor starting, low power consumption, low noise level, long life

RECIPROCATING PUMPS—stepless variable speed in a compact a-c unit

TEXTILE SPINNING FRAMES—smooth starting, stepless speed control, compactness

DRAWBENCHES—shockless load pickup, controlled acceleration, high efficiency, simplification of control

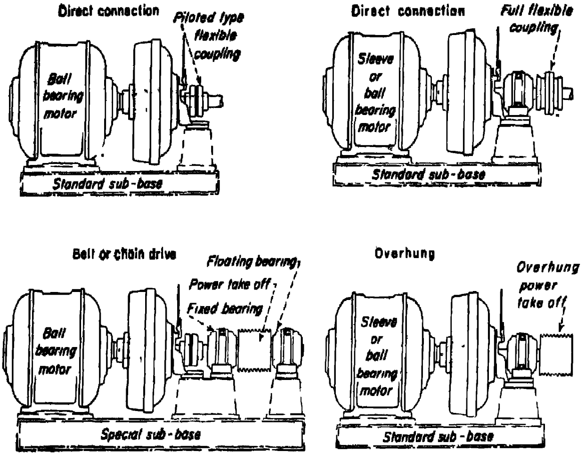

FIG. 17-4. Lever-controlled fluid drive—mounting arrangements.

CENTRIFUGALS, AGITATORS, AND MIXERS—controlled acceleration, low motor heating, no start-stop of the motor

ROTARY KILNS, DRIERS, CRUSHERS, ETC.—easy gradual starting, compact variable-speed unit

STRIP WINDING—smooth even tension, manual control sufficient

PAPER MACHINERY—stepless speed variation, responsive to process controls

Hydraulic Ratings. Ratings of the commercially available lever-controlled units are shown in Tables 17-1 and 17-2.

Table 17-2. Constant-torque Ratings

30						150-200	75-125	1620	158 0

* Strip winders, test stands, and similar special-duty machines may require special consideration

† Including oil.

NOTE: The overhung weight of the fluid drive is carried by the motor shaft. For this reason it is advisable to use standard motors with full-size shaft and bearings designed to carry this weight.

The capacity of the fluid circuit to transmit power varies as the cube of the impeller speed, the fifth power of the runner diameter, and directly as the slip (difference in speed between runner and impeller) in the lower ranges of slip.

It should be noted that the units are rated lower in some cases for fan and centrifugal-pump duty than for constant torque. This is because the safety factors employed in fan and pump selection (especially fans) tend to increase the actual load horsepower at maximum speed over the design condition, while the safety factors employed in constant-torque-drive selection create a margin of safety between the actual load and the motor rating.

Variable-torque Drives (Fans). For fan drives the speed can be varied from approximately 10 to 97 per cent speed when no stack draft is present and from about 20 to 97 per cent speed where there is a moderate amount of stack draft. The air horsepower at 20 per cent speed is 0.008 of full-speed horsepower (hp varies as rpm cubed) so that horsepower saving is no factor at low speed. The comparison curve (Fig. 17-5) shows the economy of variable-speed fan drive.

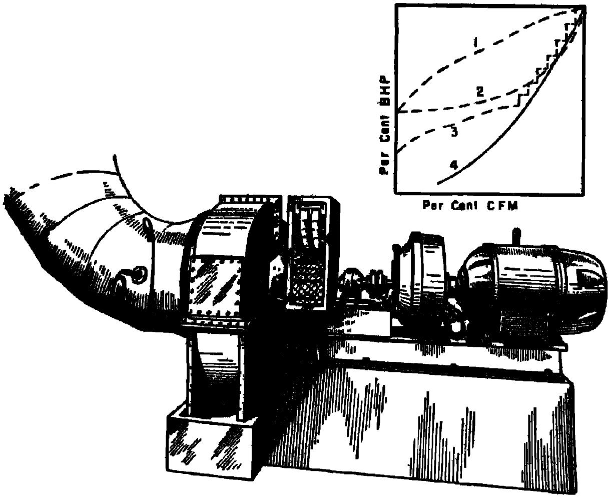

Fig 17-5 Lever-controlled fluid drive—typical fan application, and efficiency-comparison curves of fan-control devices Curve 1—outlet dampers; curve 2—inlet-vane control, curve 3—slip-ring motor and damper, curve 4—fluid drive.

Constant-torque Uses. Constant-torque loads may be divided into two classifications for simplicity.

Class 1—free-rolling loads with some momentum such as paper slitters, wire-drawing machines, centrifugals, etc.

Class 2—loads with little or no momentum or subject to torque fluctuation, such as hammermills, kilns, conveyors, vacuum filters, etc.

It is natural that all loads do not fall clearly into one or the other of these classifications, but for the purpose of analyzing speed-control range they are cited. The control range of a fluid drive is affected by torque fluctuation to a small degree at high speed and to a greater degree at low speed. It is this characteristic which makes it especially suited to overload protection and tensioning drives.

Class 1 loads may be started from standstill and run through creeping speeds very gradually. They may be operated at one-third speed and above continuously (3:1 range).

Class 2 loads may be started from standstill, but because of the usual high break-away torque, accelerate more rapidly. Fluid drives for this duty are recommended for a 2:1 speed range continuously.

	505	24⅞	12½	26⅛			25	11⅜	60 7/16				

Note: The motor selected should have full-size bearings designed for belt pull so that it can carry the overhung weight of the rotating parts. Do not use short-shaft motors without specific approval from the motor manufacturer.

Dimensions. Table 17-3 gives the approximate space required by a NEMA frame motor and a lever-controlled (variable-speed) fluid drive. Construction dimensions will vary slightly.

For dimensions of larger units apply to manufacturers.

Oil Cooler. Variable-speed fluid drives require a cooler to dissipate the heat from power absorbed at reduced speeds of the runner. The rate of oil flow to the cooler is determined by the nozzle diameter in the inner casing and may be set for the design duty. The limit of oil flow is the scoop-tube capacity since the scoop tube must be capable of handling all oil which comes through the nozzles.

Summary. To summarize the mechanical details of the lever-controlled fluid drive:

1. It is normally hub mounted on the driving motor.
2. It uses a light oil which both lubricates the pilot bearing and transmits power.
3. It can be connected to the driven machinery by flexible coupling, chain, or belt.
4. It includes an oil-to-water cooler as standard equipment.
5. It is adaptable to manual, remote, or automatic control.
6. It is built as a standard product for 1 to 350 hp.

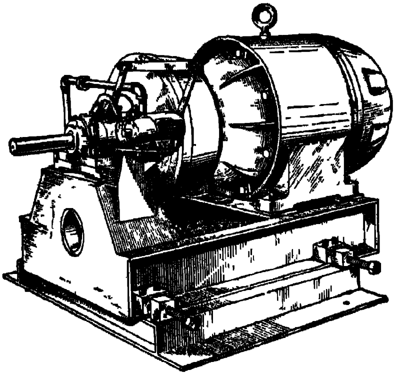

FIG. 17-6. Typical adjustable-speed unit of lever-controlled type.

Pump-controlled Fluid Drive. In general, the characteristics of the lever-controlled fluid drive apply to the pump-controlled unit. The primary differences appear in design.

1. The separate external sump or reservoir.
2. The use of a gear pump to add or remove oil from the working circuit.
3. The fixed scoop tube.
4. Larger size units handle up to 3,000 hp. A cross section (Fig. 17-7) shows the fundamental working parts.

Principle of Controlling Speed. The fixed scoop tube continually circulates oil through the external cooler circuit via the manifold. Speed control is effected by operating a small gear pump in one direction to add oil to the working circuit and, in reverse, to withdraw oil from the working circuit. When the pump is not running, the speed remains fixed. Calibrated nozzles at the periphery meter the oil flow from the vortex to the outer casing.

The pump-controlled unit is built for heavy duty—particularly for power-plant and utility service. Boiler feed-pump drives, mechanical draft, and waterworks pumps represent the bulk of the uses. Constant-torque machines falling within the ratings of these units are reciprocating pumps and compressors. The speed range for constant torque is limited by cooler selection.

Hydraulic Rating. The rating curve and dimensions appear in Tables 17-4, 17-5, and 17-6.

The horsepower transmitted by a full unit is proportional to the slip (difference between runner and impeller speed). The units are normally selected so that slip will not exceed 3 per cent, *i.e.*, the smallest unit that will fall within the 3 per cent slip rating is usually selected. The diagonal size lines in Table 17-4 indicate that hydraulic power increases as the cube of the speed and the fifth power of the diameter. (The size is the diameter of the rotors in inches.) The mechanical limits of commercially available units are listed in Tables 17-5 and 17-6.

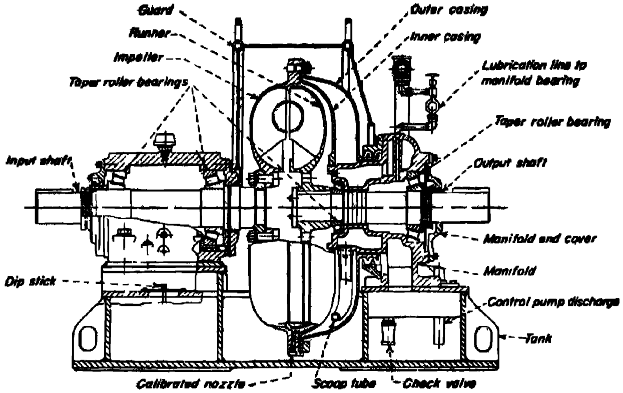

Fig. 17-7. Pump-controlled fluid drive.

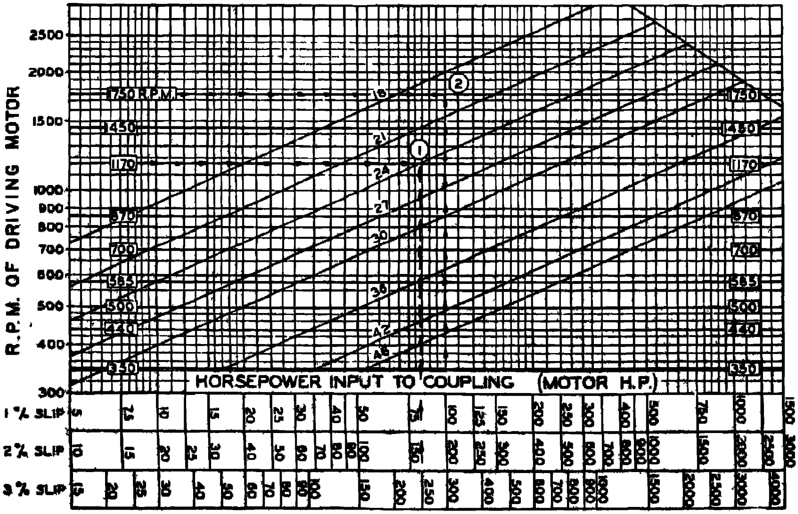
The two examples following are shown in dotted lines on Table 17-4.

Example 1: 250 hp at 1,175 rpm—size 24 VS. The intersection of the speed (1,175 rpm) line and horsepower (250 hp at 3 per cent slip) line occurs at a size 24. A size 27 would

Table 17-4. Rating Chart—Pump-controlled Fluid Drive



satisfy this load at 2 per cent slip, but there is no need to use the larger size because the horsepower and rpm limits under the dimension and rating tables show that a size 24 is rated up to 325 hp at 1,550 rpm.

EXAMPLE 2: 300 hp at 1,760 rpm. The intersection of the 1,760-rpm line and the 300 hp at 3 per cent slip line falls between a size 18 and a size 21. Since the size 18 would have more than 3 per cent slip, it is necessary to use the size 21. The horsepower and rpm limits under the dimension and rating tables show that a VS fluid drive has this rating.

A typical installation of a variable-speed fluid drive of the pump-controlled type is shown by Fig. 17-8.

Arrangements. There are two basic arrangements of medium-duty (type VS) fluid drives. Arrangement 4 is a close-coupled design in which the impeller mounts directly on the driving motor. Arrangement 8 is an independent unit which can be set in place or lifted out without disturbing the driving motor on driven machine. A full flexible coupling is required between the motor and the arrangement 8 input shaft and between the output shaft and the driven machine. The ratings and dimensions of these units are given in Table 17-5.

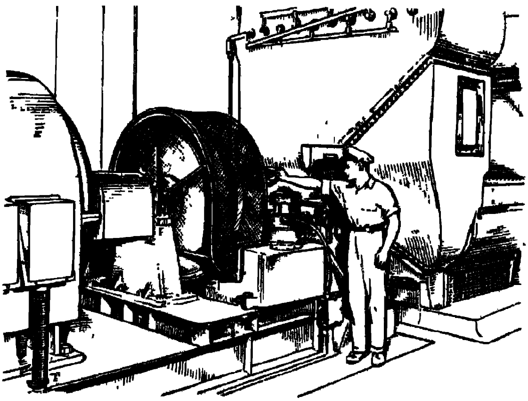


FIG. 17-8. Typical installation induced-draft fan drive.

Dimensions of heavy-duty (type PE) fluid drives are given in Table 17-6. This unit is similar to arrangement 8; it is an independent unit with its own bearings. Full flexible couplings are required to connect the input shaft to the motor and the output shaft to the load.

Duty Classifications for VS and PE Fluid Drives. *Constant-torque duty* ratings cover machines that require full torque output at reduced speeds. These loads are further classified as

Smooth-rolling loads—steady loads with considerable rolling inertia such as reciprocating pumps, printing presses, pulp grinders, beaters, and lobe blowers.

Fluctuating-torque loads—constant-torque loads subject to torque fluctuation and shock such as ball mills, tube mills, crushers, hammermills, and multicylinder compressors.

The oil-cooling requirements for these duties should be checked.

Variable-torque duty ratings cover fans, centrifugal pumps, centrifugal compressors, turbo blowers, pure liquid agitators, and similar loads. The horsepower required by these machines falls off rapidly at reduced speeds (usually as rpm^3) so that the average duty is light, and the peak duty is not in excess of motor horsepower.

Maximum ratings are based on mechanical considerations only. Fluid drive should be selected from chart of Table 17-4 with initial slip not to exceed 3 per cent. Further limitations may be imposed by oil-circulating capacity.

* For definition of variable-torque and constant-torque duty, see page 1271

NOTE: Arrangement 4 VS fluid drive has no internal pilot bearing to take thrust, and therefore the motor bearings must be capable of taking the thrust given in Table 17-5. The motor manufacturer requires thrust, overhung weight, center of gravity, and mounting details in order to design the motor shaft and bearings correctly. The motor bearings in this case must be fixed

Enclosed Design with Speed Controller. A new development is the enclosed design in which the rotors and bearings are completely encased within a stationary housing. This design embodies the following features:

1. The speed controller which makes possible the rapid and accurate response to demands of such control equipment as that used in boiler feed-water-level control.
2. Oil-film-type radial and thrust bearings supported in a split pillow block which is line-bored.
3. A heavy welded-steel stationary housing, split horizontally.
4. Integral shell- and tube-type oil coolers with removable tube bundle.
5. Forced-feed lubrication. All rotating parts and the oil piping are enclosed.

The principle of power transmission is the same for this unit as for the preceding units; the power is transmitted by a whirling vortex of oil. This vortex is set in motion by the impeller, and it imparts its energy to the runner with a smooth continuous flow of power.

Principle of the Speed Controller. There is a continuous fixed supply of oil circulated through the rotating parts by the oil pump. This oil enters the vortex and distributes itself centrifugally in the rotating parts, forming an annular ring of fluid. The speed controller skims the inner surface of this annular ring in the outer casing. Its position sets the depth (amount) of oil in the rotating parts and thus controls output speed and power.

The speed controller can be adjusted for very close accurate control. It is operated by a linkage connected to a shaft that extends through the housing. The automatic or remote manual control device is coupled to this shaft to adjust the speed controller.

The external and internal views of a 250- to 2,600-hp 3,600-rpm unit of this construction, intended for boiler feed-pump service are shown by Figs. 17-9 and 17-10. This unit is connected to the driving motor and to the driven machine by full flexible couplings.

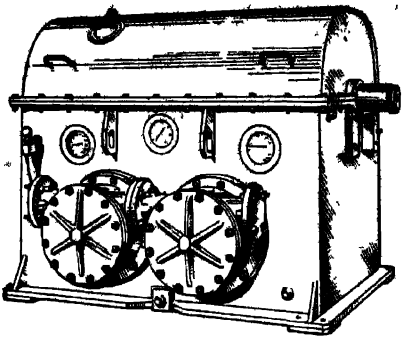

FIG. 17-9. Exterior of 3,600-rpm adjustable-speed unit.

CONSTANT-FILLING FLUID DRIVE

When a fluid drive is mounted on a general-purpose electric motor, certain new and improved characteristics result. The motor is able to start against any load and gain high speed as if started unloaded, and it cannot be stalled by overload. The motor torque can be limited to prevent shear-pin failure (for conveyors). The explanation for these characteristics is demonstrated by Fig. 17-11.

FIG. 17-10. Section through 3,600-rpm adjustable-speed unit.

Principle of Operation. The dotted lines in Fig. 17-11 are the motor torque and motor current plotted against output speed (a general-purpose motor). The heavy line beginning at the origin is the torque required by the fluid drive with the output shaft standing still. It is seen that the motor has to gain speed before the oil in the fluid drive begins to circulate and to require power from the motor. For this reason, the motor starts virtually unloaded and gains a speed where its windings are well ventilated and where the power factor is good and current relatively low before it takes hold of the load.

Applications. The applications commonly employing fluid drive and the benefits derived in each case are listed below. In most cases, the control is simplified, and the rugged general-purpose motor is sufficient.

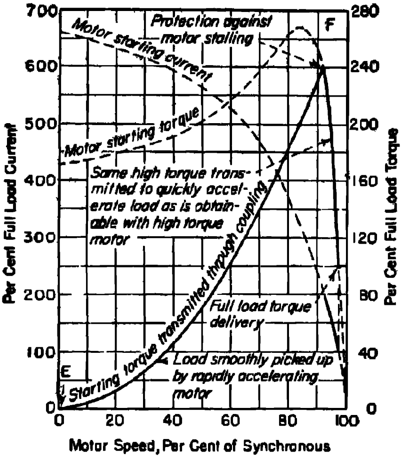

FIG. 17-11. Typical performance curve of constant-speed fluid drive and general-purpose electric motor.

AGITATORS AND MIXERS—no-load starting of the motor against a sticky mix

BALL MILLS (HEAVY STARTING LOADS)—no-load starting of the motor, low current consumption, and in some cases low demand peak (see Fig. 17-12).

CRUSHERS AND HAMMERMILLS, ETC.—shock absorption, prevention of motor-rotor troubles from jams, protection of crusher from motor impact on jams

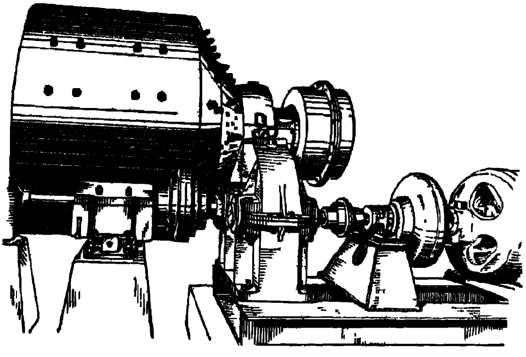

FIG. 17-12. Ball-mill application of constant-filling fluid drive.

FORGING PRESSES—hydraulic application of power

LOCK GATES—smooth starting, low peak stresses in the mechanism, shock absorption when logs get caught in the gates

CONVEYORS—Serves as a shear pin that does not need replacement, offsets bad effects of overmotoring, allows equal loading on multimotored conveyors, and gives smooth starting.

WINCHES AND CAPSTANS—simplifies control, allows the use of single-speed motors, smooth, even take-up on cable, reduces motor heating on heavy starts

Arrangements. Arrangements commonly employed are shown by Fig. 17-4. The direct-coupled arrangement can be rated for full power according to Table 17-7, but the two arrangements using a sheave on the runner shaft must be rated according to the allowable belt-pull reaction on the motor shaft.

Special motors, such as d-c motors and slip-ring motors, offer soft load pickup at low speeds and an extended speed range down to threading speeds owing to increased slip in the fluid drive (up to 100 per cent) at low motor speeds. Paper slitters, hoists, and winches sometime employ this characteristic of fluid drive.

Hydraulic Ratings. The ratings at various speeds are shown in Table 17-7. Since power varies as the cube of the speed (also the fifth power of the diameter), the most economical unit is a high-speed installation. For this reason, this drive is almost invariably mounted on the electric-motor shaft.

Table 17-7

* Rapid start-stop cycles require special consideration.

† High-slip motor full-load speed.

Where two ratings are shown for one size of fluid drive, any rating between these two can be used

NOTES: Ratings shown in lightface type are satisfactory for continuous operation at full load. The ratings shown in boldface type are for intermittent duty only Since there is no means of cooling the oil except by radiation, continuous operation at full load for these ratings will cause excessive oil-temperature rise and may necessitate use of cooling means. If the motor is only partially loaded or if the full load is applied for short periods of time only, the temperature rise will not be excessive. Severe start-and-stop cycles require special analysis of heat dissipation.

Dimensions and Mechanical Ratings. The dimensions of commercially available units are shown in Tables 17-8 and 17-9.

Internal-combustion-engine Applications of Constant-filling Type. The automobile has so thoroughly demonstrated fluid drive that not much in the way of performance in connection with internal-combustion engines is unexplained today.

The value of this drive can be summarized as (1) smooth load pickup, (2) extended engine speed range, (3) protection of machinery against overload, (4) the engine cannot be stalled, and (5) the engine torsional vibrations are dampened in the oil vortex.

The industrial applications cover switching locomotives, power shovels, cranes, logging machinery, tractors, road rollers, compressors, earth movers, trucks, and almost any engine drive. The ratings of commercially available units are given in Table 17-10.

EXAMPLE 1: 55-hp engine at 1,600 rpm driving a compressor at nearly constant rpm. Under the column for 1,600 rpm, the T-300 is rated at 57 hp. Therefore, this is the correct size

EXAMPLE 2: 275-hp engine at 1,120 rpm for main propulsion of a tugboat (variable-torque load). By interpolation between the 1,100- and 1,150-rpm columns, it is seen that a T-540 has the required capacity.

Hydraulic Ratings Based on Engine Torque. Another method of selection, most commonly used for all but constant-speed drives or marine drives, is on the basis of

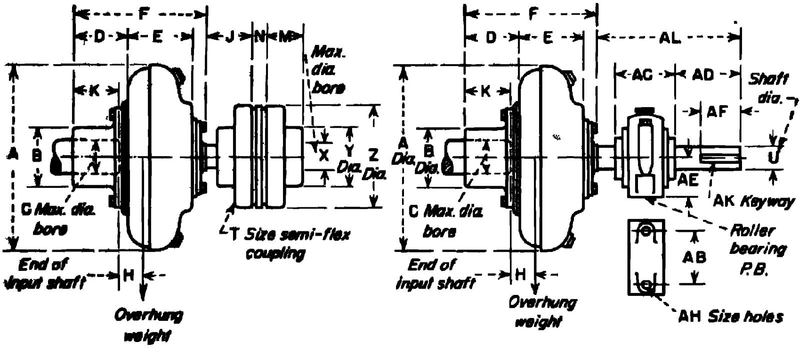
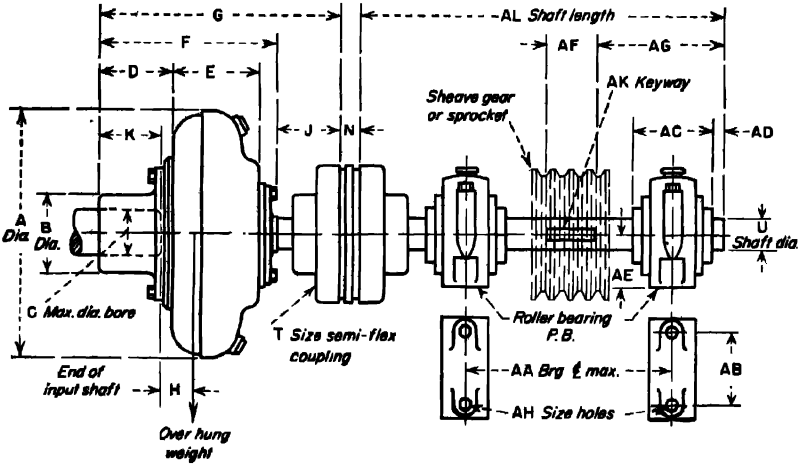
engine torque and the useful operating range of the engine. The method is shown by a typical engine curve (Fig. 17-13).

The engine torque output vs. speed is relatively constant. The drive should be so selected that it allows the engine to be pulled down under full load, only to a safe minimum engine rpm. This point determines the selection of the drive. On the basis of engine torque and minimum engine rpm, commercial sizes can be selected from Table 17-11.



Arrangement 4A

Arrangement 4B



Arrangement 4C

Fig. 17-12a. Arrangements 4A and 4B for Table 17-8 and Arrangement 4C for Table 17-9.

It will be noted that the operating slip is in the order of 5 per cent or less throughout the normal range of engine speeds and that at partial throttle the slip decreases. The square curve labeled "starting torque" is the torque developed at 100 per cent slip by this drive. It is this gradually rising torque which gives such excellent "feathering" action and which permits the engine to be cranked against the connected load.

Applications Based on Engine Torque. Applications usually selected by this method are fluctuating loads which require full engine torque at reduced speeds. Examples are vehicles, excavating equipment, and engine-driven hoists and winches.

Applications usually selected by this method are (1) those which run at or near constant speed such as generator sets, reciprocating compressors, (2) variable-torque loads such as centrifugal pumps, turbo blowers, ship propulsion, and similar duties where torque falls off rapidly at reduced speeds. To select a fluid drive, look under the vertical columns for the governed speed, and find the horsepower rating. If it falls between two sizes, select the larger size fluid drive (from the column at left). For loads using full engine torque at low speeds, select on the basis of engine torque from Table 17-11.

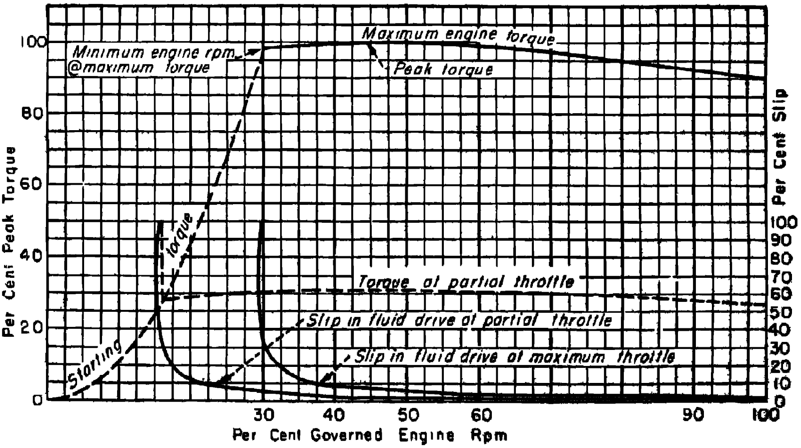

FIG. 17-13. Typical performance curve of fluid drive and internal-combustion engine.

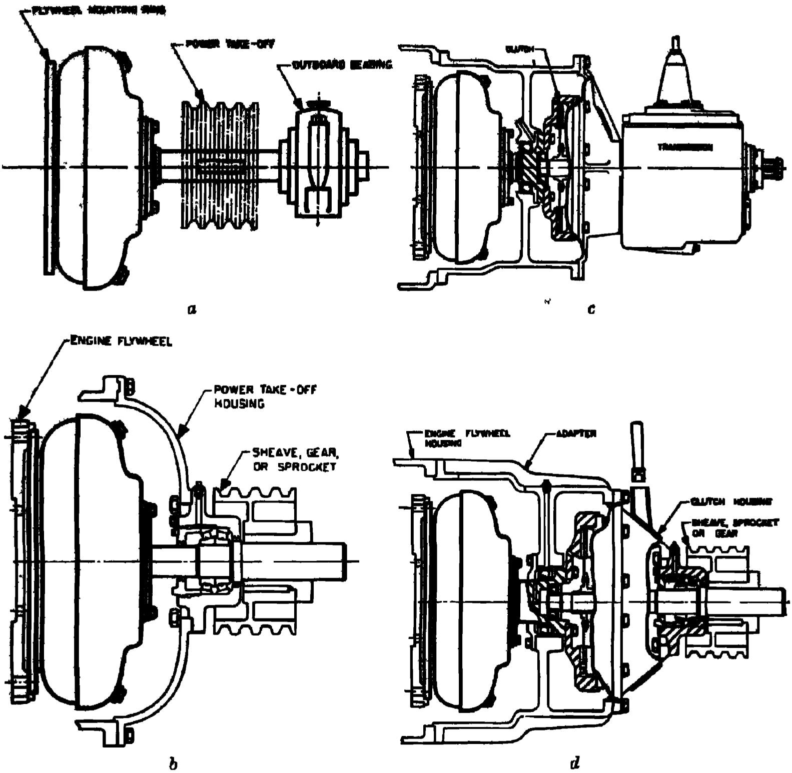

Fig. 17-14. Mounting arrangements—internal-combustion-engine applications of fluid drive.

Table 17-11. Minimum Engine Rpm = Per Cent Speed Factor × Governed Rpm

Type of engine	Per cent speed factors		
	Light duty—cranes, locomotives, trucks, winches	Medium duty—tractors, scrapers, reciprocating pumps	Heavy duty—power shovels, yarders, bulldozers, mine hoists
High-speed-wide-range engines which idle well at less than 20 per cent of governed speed....	35–40	30–40	
Medium-high-speed engines which idle well at less than 30 per cent of governed speed . ..	40–50	35–45	35–40
Slower speed continuous-duty engines which idle at a relatively high per cent of governed speed	.. .	40–50	40–45

Table 17-11 shows the per cent of governed speed at which rated torque must be developed. Table 17-12 shows the torque transmitting capacities of the various size fluid drives at minimum engine rpm.

The selection of a fluid drive by this method is based on (1) the rated torque to be transmitted and (2) the minimum engine rpm at this rated torque. The minimum engine rpm is the point at which the output shaft of the fluid drive stalls under *maximum engine torque*. (Figure 17-13 illustrates this graphically.) To select a fluid drive from the Table 17-11, find the desired minimum engine rpm at maximum torque from the per cent speed factor table. Enter the rating table in the speed column corresponding to the calculated minimum engine rpm, and select the fluid drive that will transmit the engine torque at that speed.

High minimum engine speeds should be avoided as they increase the fuel consumption of the engine and the working temperature of the fluid drive. Some field adjustment is available in the initial oil filling of the drive.

Table 17-12. Rated Torque at Minimum Engine Rpm

Fluid-drive size	Rated torque, ft-lb

T-390		205	260	320	385	460	540	625	720					
T-420	228	300	380	465	565	675	790	910						
T-480	445	590	740	910	1,100									
T-540	790	1 030	1 300											

Arrangements. The mounting arrangements are shown in Fig. 17-14. The engine can be cranked against the connected load with *fluid drive* so that a clutch is not necessary for starting the engine. However, a clutch is required wherever it is necessary to disconnect the engine from the load, as in shifting a transmission or in hoisting (crane operations). The friction clutch can be part of the engine power unit, as is the case with the unit-mounted transmission, or it can be incorporated in the power take-off pulleys or the hoist drum as is often done on oil rigs.

HYDRAULIC TRANSMISSION—POSITIVE DISPLACEMENT TYPE*

BY RANSOM TYLER

Engineering Department, The Oilgear Company

Hydraulic transmissions of the positive-displacement type make use of energy carried in a body of fluid under pressure to perform work. The great use made of this type of transmission has been brought about by the ease with which this energy can be transmitted to points that are otherwise difficult of access and by the precision with which control can be accomplished.

HYDROSTATICS

Since the energy transmitted is primarily pressure energy, transmissions of this type are sometimes known as "hydrostatic transmissions" as contrasted with fluid couplings or torque converters which make use of the principles of hydrodynamics.

Pressure. Pressure is the stress within a fluid. Since a fluid has no tensile or shear strength, pressure is a purely compressive stress. The pressure of a fluid causes a force to be exerted on any solid surface with which it is in contact. This force is always exerted at right angles to each element of any such stationary surface.

Pressure can be produced by squeezing a volume of fluid confined in a vessel or, since the fluid has a definite density, by the elevation of a portion of a continuous body of fluid above another portion. The character of the pressures produced in either manner are identical and, in fact, in hydrostatic transmissions, portions of the fluid are under pressure produced by both methods simultaneously. However, in most transmissions the pressure produced by elevation is insignificant in comparison to the pressure produced by compression, and the net energy from elevation is nil since the transmission operates in a closed circuit.

Atmospheric Pressure. The atmosphere is a fluid that has density and elevation. Thus at any point there exists a definite atmospheric pressure similar in character to hydraulic pressure. While this pressure varies from time to time and from point to point, atmospheric pressure (except for aircraft) can be considered to be the standardized value of 14.7 psi, or 760 mm Hg. This suggests various methods of measuring pressure: (1) in units of force per unit of area, F/A; (2) in units of length or height of the fluid surface above the point considered; or (3) as a multiple of the pressure of a standard atmosphere.

Absolute Pressure. Absolute pressure is the stress above zero in the fluid. Thus, at any free surface the absolute pressure is considered to be equal to atmospheric pressure at that point. (This is slightly modified owing to surface tension, but this has no significance in the theory of transmissions.) Since hydraulic transmissions operate in a closed circuit, all effects of atmospheric pressure are canceled out, and gauge pressure, or the pressure above or below atmospheric, is used rather than absolute pressure. Thus, except that there is a limit to negative gauge pressures, dependent upon the value of atmospheric pressure, the existence of atmospheric pressure can be neglected if all pressures are considered to be gauge pressures.

Pressure Head. Fluid in a vessel or pipe that is under pressure owing to the elevation of another portion of the fluid is spoken of as having a head. Pressure head, then, follows as the pressure (measured in units of height of the given liquid) produced by this head. It is related (see Fig. 17-15) to the pressure as measured in units of force per unit of area through the density of the fluid thus:

---

* Superior number refers to specific reference listed at the end of this subsection.

$$(P = F/A = \delta H)$$

where δ = density (weight per unit volume)

H = head in units of length or height of free surface above point considered

Suction Head. The gauge pressure is positive or negative depending upon whether the equivalent free surface is above or below the point to be considered. Pumps or similar apparatus frequently take their supply from bodies of fluid, the free surface of which is below the pump. The suction head is the negative pressure expressed in feet of head at the pump intake. With no flow through the suction line, this is equal to the distance below the pump inlet to the free surface.

The importance of suction head lies in the limit to its value. Since a fluid has no tensile strength, the pressure cannot be less than absolute zero. Thus the absolute limit of suction head is atmospheric pressure at the place in which the device is to be used. Most manufacturers will give a practical limit as to the suction head at which their equipment is capable of satisfactory operation. This is expressed in units of height, so if a significant change is made in atmospheric pressure, such as operation at high elevations above sea level, the limit must be modified accordingly.

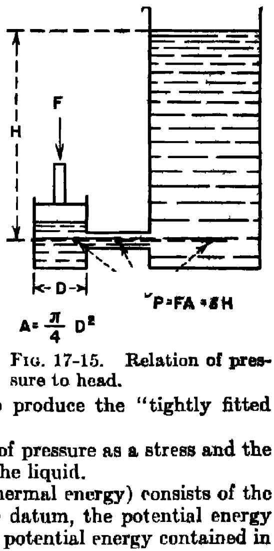

Fig. 17-15. Relation of pressure to head.

Pascal's Theorem. One of the great functions of hydrostatic transmissions is the multiplication of forces. Hydrostatic transmissions are unique in possessing the property of easily converting small forces into great ones or, conversely, short motions into long ones. This property was first recognized by Pascal, who enunciated it thus: "If a closed vessel of fluid have a hole of unit area closed by a closely fitted plunger, and a second hole of one hundred units area also closed by a closely fitted plunger, then one man exerting a force on the smaller plunger can equilibrate the force exerted by one hundred men against the other, and can overcome ninety-nine." While this is the principle of the hydraulic press, as well as many other hydraulic applications, no practical use could be made of it for over a century because, until the invention of the hydraulic packing by Bramah, no way was known to produce the "tightly fitted plunger."

This, of course, follows naturally from the concepts of pressure as a stress and the equality of pressure in all directions at a point within the liquid.

Energy. The energy in a fluid at rest (excluding thermal energy) consists of the sum of the potential energy due to its elevation above datum, the potential energy due to the pressure to which it has been raised, and the potential energy contained in the fluid as elastic energy. A fluid transmission is normally a closed-circuit device, and the fluid used for power transmission passes around the circuit and eventually reaches the point from which it started. Since fluid fills the circuit, each element reacts against the next, and the energy of elevation, so far as the transmission is concerned, is canceled out.

Pressure Energy. The potential energy of pressure was for many years the basis of practically all hydraulic applications. Hydraulic energy was stored in weighted accumulators and used as required. The potential energy thus stored was equivalent to the product of the quantity of fluid which can be discharged by such an accumulator and the pressure which is raised by the accumulator. This is illustrated by Fig. 17-16.

Elastic Energy. While liquids are frequently defined as incompressible fluids, and they are so when contrasted to vapors or gases which are compressible fluids, they all possess a considerable degree of elasticity. The hydraulic fluids used in fluid transmissions have an elasticity which is most conveniently expressed as a percentage change in volume as pressure is changed by a given amount. The fluids used have an elasticity, under working conditions, on the order of ½ per cent per 1,000 psi pressure change. This percentage decreases slightly when pressures in excess of 1,000 psi are used, becoming about ¼ per cent per 1,000 lb pressure change at pressures on the order of 50,000 psi. While the energy stored in this form is not ordinarily a large quantity, it should be noted that this elasticity is roughly 100 times that of steel, and since the normal pressures used are much less than the stresses applied to steel, the energy is stored in the manner of a slightly compressed spring. This property is important in considering the rigidity of a transmission system or in designing the valving to release pressures on a quantity of liquid. This is discussed in greater detail (see Cylinders and Valves).

HYDRODYNAMICS

While the basic principles utilized by positive-displacement transmissions are those of hydrostatics, it is necessary that motion of the fluid take place in order to obtain work from the transmission. The velocity imparted to the fluid produces dynamic effects which modify the purely hydrostatic principles.

Any mass in motion possesses a kinetic energy equivalent to $\frac{1}{2}(W/g)V^2$ in which W/g is the mass and V the velocity.

Velocity Head. If the moving mass is a fluid, it gains this kinetic energy at the expense of the potential energy it possessed while at rest. The potential energy converted to kinetic energy is equivalent to the weight of the fluid element multiplied by the pressure head (vertical distance it could fall) required to impart the velocity to the fluid.

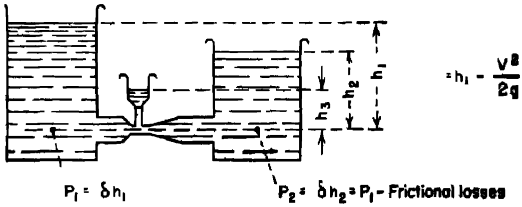

FIG. 17-17. Venturi effect.

Since these quantities must be equal,

$$Wh = WV^2/2g \qquad \text{or} \qquad h = V^2/2g$$

Since $V^2/2g$ is equal to the head required to produce the velocity, this quantity is named the velocity head.

Venturi Effect. Since the velocity head in a moving fluid is produced at the expense of the pressure head, the static pressure at a point in a moving fluid is less than the static pressure in the body of fluid supplying the moving steam.

This is of considerable importance in analyzing the dynamic effects of fluids at high velocities, especially during the critical range of opening or closing valves, etc.

It will be noted from Fig. 17-17 that the kinetic energy of velocity head is reconverted to the potential energy of pressure head when the moving mass is brought to rest. Thus the pressure at one point in a hydraulic circuit may be at a lower pressure than at adjacent points on either side.

Fluid Friction. Whenever a particle moves in relation to an adjacent particle, there is an energy conversion due to friction. This is true regardless of the physical state of the particle—solid, liquid, or gaseous. Therefore, in a moving fluid there is a decrease in pressure equivalent to the amount of energy converted into heat. This subject is covered quantitatively under Piping, Valves, and Fittings (Section 11).

Fluid Friction in Hydraulic Piping. The usual method of sizing hydraulic piping is the rule-of-thumb method based on the velocity of the fluid in the pipe. This is ordinarily adequate for the high-pressure piping in the majority of hydraulic installations, as the lines are short, and the losses are low compared to the pressures to be used. Pipe-line velocities are considered to be within the limits of best practice if held to 12 fps for the smaller pipes (1 in. or smaller) and 15 fps for larger pipes. These limits are exceeded for momentary restrictions or for portions of a cycle in which head loss is of little importance, but 20 fps is seldom exceeded since the danger of dynamic effects in valves, heating of the fluid, and hydraulic shock increases rapidly with velocity.

The rule-of-thumb method should be used with great caution, if at all, for sizing low-pressure or suction lines. When conditions are good, the lines straight and short, and viscosities are not high, velocities of 5 to 7 fps are sometimes used. However, a preferable method is to determine the actual head loss. The head loss in a pipe line is a proportional function of a fluid-friction factor, the equivalent length of the pipe, the density of the fluid, the square of the velocity, and is inversely proportional to the actual inside diameter of the pipe. The fluid-friction factor is a function of Reynolds number (diameter times velocity divided by kinematic viscosity), and the equivalent length takes into account the effect of bends, elbows, valves, etc.[1]

The most convenient method of solving this rather complex equation is by means of curves or alignment charts. Fig. 17-17*a* shows a set of curves made up for one specific viscosity condition (200 SSU). Fig. 17-17*b* is an alignment chart showing equivalent length of fittings.

While the head loss through piping is subject to variation with varying viscosities, it is characteristic of a sharp-edged orifice of proper proportions that it is almost independent of viscosity variations if the critical velocity is exceeded. Fortunately, the critical velocity is within most normal limits except for very small orifices, very small flow, or very high viscosities. The orifice should be no larger than one-quarter the diameter of the pipes on either side, which should be straight and uniform for at least 20 diameters on either side. The length of the orifice should be less than 0.4 its diameter to be considered sharp-edged. When these conditions are met, the pressure drop through the orifice can be approximated by

$$P = 0.015V^2$$

where P = pressure drop, psi

V = velocity through the orifice, fps

This feature of independence of viscosity through normal working range makes the orifice a useful control device where its pressure characteristics permit.

Water. Clear water is used in certain hydraulic presses and similar apparatus. In apparatus for which it is designed, it serves its purpose, being easily available and cheap. However, it must be used with care in climates in which the temperature falls below the freezing point; and the equipment is subject to rusting, especially if idle.

Water Emulsions. Soluble oils are frequently used in conjunction with water to lessen the danger of rust and corrosion. They also provide a degree of lubrication for rubbing surfaces. The dangers of freezing, however, are still present with this fluid, and it has not sufficient lubrication for use in high-speed rotary pumps and like equipment.

Oil. The properties of oils are discussed under Lubrication. Aside from selecting an oil of proper viscosity range, the factors that are important for transmission service are a high viscosity index, good stability for long life, an emulsibility rating that will

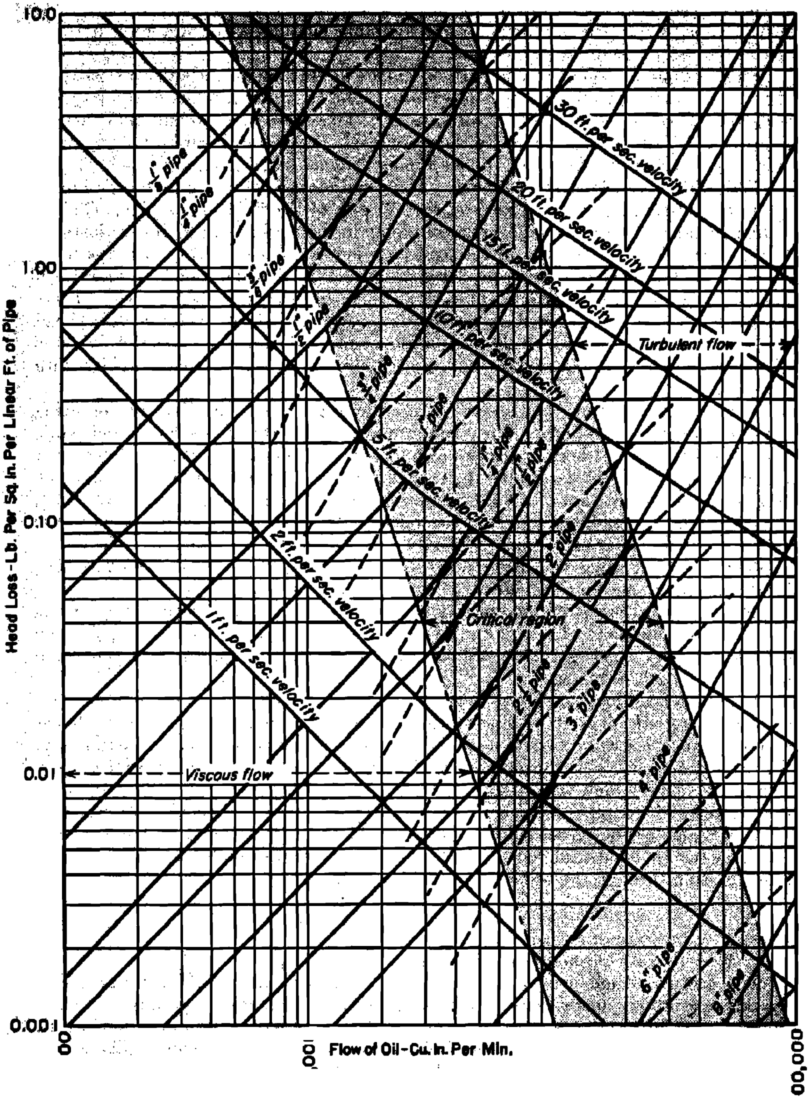

FIG. 17-17*a*. Head loss in pipes for oil at 200 SSU.

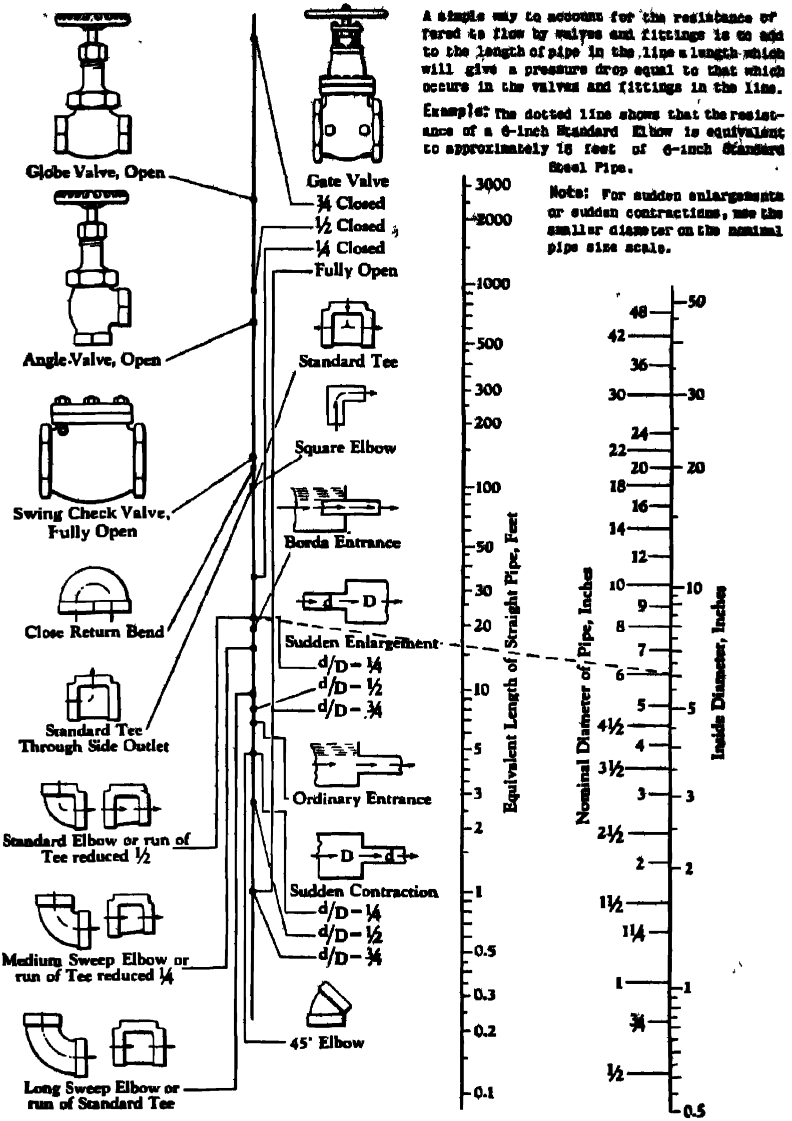
assure rapid release of entrained air, and a neutralization number that indicates that it will be free from corrosion elements damaging to the equipment with which it is used.

Oil Maintenance. Just as the initial selection of the oil has an important bearing on the performance and life of many systems, so the maintenance of the properties of the oil is of importance if performance is to be maintained and the expected long life realized. Contaminated oil is the foe of wearing surfaces and a major cause of



A simple way to account for the resistance offered to flow by valves and fittings is to add to the length of pipe in the line a length which will give a pressure drop equal to that which occurs in the valves and fittings in the line.

Example: The dotted line shows that the resistance of a 6-inch Standard Elbow is equivalent to approximately 16 feet of 6-inch Standard Steel Pipe.

Note: For sudden enlargements or sudden contractions, use the smaller diameter on the nominal pipe size scale.

FIG. 17-17b. Equivalent length of pipe fittings. (*Courtesy of Crane Co.*)

sticking of closely fitted valves and controls. Every effort spent in "good housekeeping" about a hydraulic system will be repaid by a longer, more trouble-free life of the equipment. Care should be exercised especially during the initial setup of the equipment or when the units or piping are opened for repair that all open holes are protected against the entrance of dirt or water and that the oil for filling is handled in clean containers and protected against contamination during the process.

If hydraulic systems are to be operated in dusty atmospheres, the breathers should be protected by air filters or equivalent protectors. In excessively humid atmospheres, it may be necessary to pipe the breathers into a drier, cleaner room to prevent condensation contamination.

In spite of all precautions, many systems become contaminated from breakdown of the oil and the entrance of external contaminants in spite of the protective devices. Oil filters are of great value in such cases and often save many times their cost in preventing shutdown and repairs. The manufacturer's recommendations as to the proper type of filter and its location in the circuit should be followed.

Oil oxidizes and breaks down when agitated in contact with the air. This process is greatly accelerated with increasing temperatures. Heat exchangers or coolers are of great benefit in those systems which operate at high temperatures. The installation of water coils in an oil reservoir is generally very inefficient and often dangerous because of condensation on uncovered portions of the coil. Generally a commercial heat exchanger will save enough water to justify its cost over a water coil.

When cooling water is difficult to obtain, use can be made of oil-to-air heat exchangers, a standard unit heater being used for the purpose.

HYDRAULIC POWER EQUIPMENT

The elements forming hydraulic-transmission circuits are pumps, motors, control devices, auxiliary equipment, and instruments. An understanding of the characteristics and limitations of the elements used is essential to an understanding of the circuit.

Positive-displacement Pumps. Of the several hundred general classifications of pumps listed in a mechanical catalogue, only a relatively few are suitable for power-transmission purposes. However, these few types are offered in a considerable variety of designs. There may, therefore, be individual exceptions to some of the following statements concerning characteristics and limitations of any particular type of unit. For power transmissions, pumps are made to be either a constant-displacement type or a variable-displacement type. All principal types of construction have modifications which permit their use either as constant- or variable-displacement pumps. However, some types are essentially better adapted to be constant than variable.

In order to achieve a successful system, it is necessary not only to design the suitable circuit or connections between units but also to select circuit elements having characteristics that most nearly match the requirements of the work to be performed. In comparing the applicability of various types of pumps, the following characteristics should be weighed, and the pump selected that will provide the best over-all performance at the least cost. Among the most desirable performance characteristics are

1. Capacity to deliver the required amount of fluid
2. Pressure rating sufficient to perform the work
3. A high-pressure overload capacity
4. Low slip, so the output will be maintained over wide ranges of load
5. Ruggedness to stand abuse
6. Minimum size
7. Input speed to match the prime mover
8. Dependability to ensure continuity of service
9. Accessibility to facilitate repair
10. Self-priming ability
11. Ease of control for those types having controls
12. Freedom from pulsations in output
13. Quietness
14. High efficiency
15. Cost

Crank and Piston Pumps. (See Fig. 17-18.) The crank and piston pump is the type first developed. It is essentially the hand piston pump modified by the addition of a crankshaft and connecting rod to permit the application of power. Pumps of this type are adaptable to the use of any fluid that can be pumped. They are rugged and dependable and can be easily understood and serviced by any mechanic. They are capable of being manufactured in any practical capacity or pressure rating. They are, however, of considerable weight and bulk in comparison to their capacity, usually require a considerable reduction in speed between prime mover and crankshaft, and frequently require considerable maintenance to keep the packings from leaking, the bearings tight, and the valves in condition. Most of these pumps impart a noticeable pulsation in line flow and pressure.

The principal design modifications are in the number of plungers—single- or double-acting plungers, horizontal or vertical arrangement—and in details of valve design. A modification to produce variable displacement is available which utilizes a variable-ratio element between the crankshaft and the connecting rod.

When well maintained, the volumetric efficiency of these pumps is quite high, but the mechanical efficiency is often rather low, bringing the over-all efficiency on the average to perhaps 60 to 75 per cent.

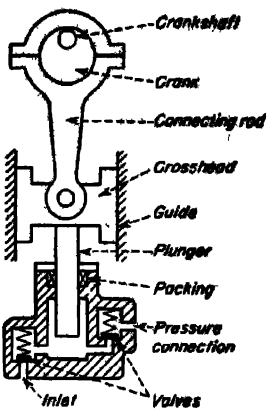


FIG. 17-18. Crank and piston pump.

Gear Pumps. (See Fig. 17-19.) The gear pump is a simple and inexpensive pump. It depends for its action on a pair of gears closely fitted in a housing. Fluid enters the tooth spaces on the inlet side as the teeth disengage, is carried around to the outlet side by the tooth spaces, the teeth forming a seal against the housing, and is forced out of the tooth space by the engagement of the teeth on the pressure side.

Gear pumps are ordinarily limited to medium- or low-pressure service, although some precision pumps are made for pressures up to 2,000 psi. They can be made to pump many different fluids. They are small in relation to their capacity and, when pumping a light lubricating oil, can be made to run at high speeds which permit direct coupling to a standard electric motor. Gear pumps are usually self-priming up to moderate suction heads. The ordinary gear pump imparts a rather severe high-frequency pulsation to the output, and this is one of the principal reasons it is usually rather noisy. Many variations in tooth design and other arrangements have been made to reduce this factor and to reduce trapping of the fluid in the gear spaces. This trapping, which is quite severe with standard involute gear teeth, results in considerable loss in efficiency.

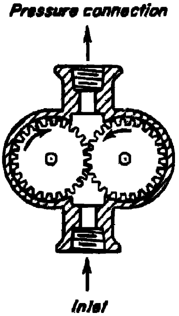

FIG. 17-19. Simple gear pump.

Many modifications in the design are available, among them the use of helical or herringbone teeth; internal gears; special tooth [illegible] some requiring the use of timing gears; and the use of [illegible] wide-face gears to form the "screw" pump. One modification uses a [illegible] form, together with drilled holes to the face and root of each tooth connected with a ported shaft to obtain freedom from trapping and [illegible] of variable output. By rotating the shaft, the oil trapped between the teeth can be discharged into either the pressure or the suction line, thus subtracting from the amount carried around by the teeth and providing a means of varying the delivery. Figure 17-20 illustrates this principle.

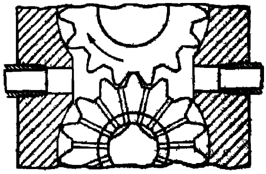

FIG. 17-20. Nontrapping type of gear pump.

Radial-piston Rotary Plunger Pumps. The radial-piston rotary plunger pump was designed primarily to provide an accurate and easily controlled source of variable flow. The pumping action depends upon eccentric action to reciprocate pistons in a rotor as both rotate relative to a ported valve element. The degree of eccentricity can usually be varied by any one of a variety of controls, although pumps of fixed eccentricity are also produced. Figure 17-21 illustrates the principles of this type of design.

Pumps of this type are available in capacity ranges from one to several hundred gpm and pressure ratings from 1,000 to 5,000 psi. Since they were produced primarily to provide a controlled output, their slip is low, and they are well and accurately made, thus providing long life. The input speed is generally suitable for direct coupling to standard motors, and the size is not excessive for industrial purposes. The large number of pistons cuts down the pulsations in the output, and the noise level is tolerable in most cases. Some of the smaller pumps can be considered practically noiseless. This type of pump shares with the axial-piston rotary pump the distinction of having the highest efficiencies obtainable in pumps.

Since these pumps are generally produced in the variable-displacement type, they come equipped with stroke control devices. These may be manually operated or arranged for automatic or remote control responsive to electric switches, line pressure, or the motion of pilot valves.

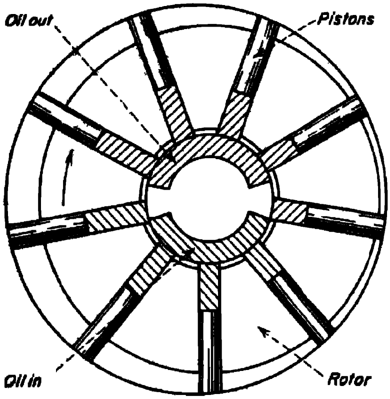

FIG. 17-21. Radial-piston rotary plunger pump.

FIG. 17-22. Axial-piston rotary plunger pump.

A design modification makes use of an elliptical cam track to provide two piston impulses per revolution, thus obtaining a hydraulically balanced unit. Displacement variations are obtained by rotating two adjacent cam tracks relative to each other and to the valve ports so that one set of pistons adds to or subtracts from the other.

Axial-piston Rotary Plunger Pumps. Axial-piston rotary plunger pumps obtain their pumping action by the angularity between the axes of a cylinder barrel containing the pistons grouped about its axis and a reaction member controlling the longitudinal position of these pistons. Figure 17-22 illustrates this principle.

Characteristics of these pumps and the uses for which they are especially suitable are very similar to the radial-piston pumps described above.

Vane Pumps. Vane pumps obtain their pumping action from vanes which push the fluid trapped between them across the seal between the suction and pressure ports. The shape of the housing containing the rotor and vanes is such that the vanes are retracted within the rotor while passing the pressure port, so that very little fluid is carried from the pressure to the suction port. Figure 17-23 illustrates a type of vane pump having a cam-shaped housing, or vane track, and two suction and two pressure ports. Each vane thus performs two pumping functions each revolution, and the hydraulic forces on the rotor are balanced. Many designs of vane pumps have been produced. However, the ones having the chief differences from the above are those providing variable displacement. One design uses a circular vane track with variable eccentricity. Another has sliding members and articulated guides to vary the shape of the vane track.

Vane pumps have been limited in capacity by the maximum rubbing speed permissible on the vane tips and by the port area limitations. Pressure has been limited by the strength of the vane and rotor. The maximum capacity of present models is limited to about 55 gpm and 1,000 psi per rotor. These pumps are characterized by low slip, small size, and ability to run at standard motor speeds. They are self-priming and have very smooth output characteristics. They are quiet in operation and have a high efficiency.

While they are somewhat sensitive to pressure overloads and are somewhat short lived under continuous full-load conditions, they may be repaired or replaced easily and also at a low cost.

Motors. Hydraulic motors are of three general types, depending upon the type of work to be done by them. The linear motor, or cylinder, is preferred for operations requiring motion in a straight line or through a small arc, such as presses, lifts, machine-tool slides, pushers and transfers, etc. Rotary motors find their greatest use in driving the shafts of printing presses, conveyors, testing machines, mixers, or any other device in which the speed must be changed while keeping the input speed constant or where a constant output speed is required with a variable-speed input.

Oscillating types of hydraulic motors have been produced for special purposes. However, their use is not widespread, and no designs of this type have been standardized.

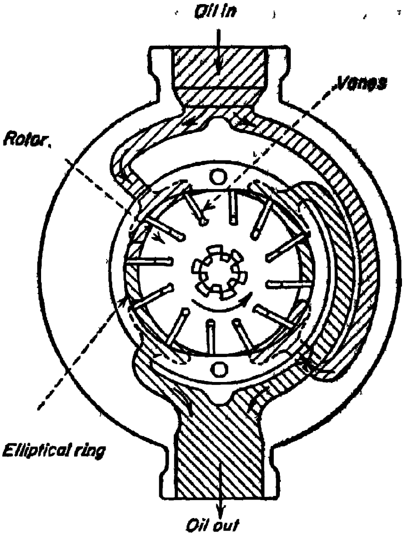

Fig. 17-23. Constant displacement, balanced vane pump.

Hydraulic Cylinders. Hydraulic cylinders are the oldest, simplest, and the most frequently used of the hydraulic-transmission motors. They are available in many standard types and sizes, and special sizes and types are easily and quickly made when needed. Many cylinders are made integral with the machines they operate. Cylinders may be single acting (delivering power in one direction only) or double acting (capable of exerting force in both directions); differential (having unequal areas exposed to the pressure fluid in opposite directions) or nondifferential (with equal areas on each side of the piston); plain or cushioned; and may be had in a variety of mountings or with practically any type of pipe connection (see Fig. 17-24).

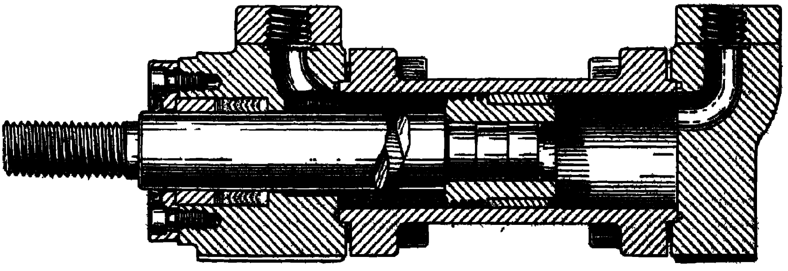

Fig. 17-24. Double-acting hydraulic cylinder.

A cylinder consists essentially of a tube, which may be rough for single-acting cylinders of the most usual type; a smooth ram; a ram-packing gland; a ram packing; a piston and piston packing (not essential for single-acting cylinders); mounting devices; and pipe connections.

The cylinder tube may be of any suitable material and may be open at both ends requiring a head to close it or closed at one end. It is essential that the tube be liquid-tight and have dimensions such that the ram assembly can slide freely. It must, of course, have sufficient strength to withstand the greatest pressures to which it will be subjected. The tube or the heads attached to it carry the mounting devices. These may be lugs, feet, flanges, eyes, trunnions, or recesses for a saddle.

The ram must be smooth, straight, and of uniform diameter so that it can easily slide within the tube. In a single-acting cylinder the diameter of the ram and the pressure used determine the force which the cylinder will exert. In a double-acting cylinder the difference between piston area and the ram area determines the working area in the pulling direction, while the full-bore area may be used for pushing. Valving can be arranged so that the pushing and pulling areas may be connected, permitting selection of either full-bore area or ram area only to provide two tonnages and two rates of speed. The operation with the two areas connected is referred to as "differential advance." The ram must have sufficient strength to withstand the forces and be of sufficient rigidity so that it remains in alignment at all times so that the packing will not be worn.

The packings are perhaps the most critical items in the cylinder. The usual type of ram packing is a material that is impervious to the fluid, can be formed to fit the ram closely, and has sufficient pliability to conform to minor imperfections in the ram surface as it slides through. They are therefore generally made of such materials as leather, treated hemp, asbestos, or a moulded composition or rubber. A gland is often used to apply a pressure on the packing. The adjustment of the gland is critical, since insufficient pressure will permit leakage, while excessive pressure causes excessive friction, heat, and possible packing failure. Several types of self-adjusting packings are available. These are formed in the shape of cups, Vs or Us, so that the pressure against them expands them against the walls of the ram to seal the fluid. When properly installed, these require no adjustment throughout their life.

Self-adjusting packings are also used as piston packings. Expanding metallic piston rings are another frequently used piston packing. While these are subject to some leakage, they have a longer life and require no adjustment or other attention.

Cylinders are easily understood and easily maintained. Their application requires only the selection of a size that will give the required force and stroke. Their limitations are few. They must apply their power in a straight line, and they must not exceed a length at which the ram will deflect excessively. In actual practice this deflection must be kept quite small to avoid excessive packing wear.

For some applications the elasticity of the oil column limits the practical length of the cylinder. Movements requiring rigid coupling, such as machine-tool feeds operating at slow speeds, should be strictly limited as to length. The difficulty appears as jump, chatter, or gallop of the moving member and is caused primarily by variations in the working load. These load variations may be characteristic of the work being done or may arise as a result of the difference between static and moving friction between the moving parts. The characteristics of this jump are greatly affected by the character of the load, the type of guiding, the mass of the moving parts, lubrication, alignment, adjustment of packings, etc., and by the type of circuit used to suppress the jump. A first approximation as to the amplitude and frequency of the jump can be obtained by estimating the working pressure and applying the compressibility factor of ½ per cent per 1,000 psi to the length of the oil column. The maximum stroke length can be used as an approximate length for the oil column if the connecting pipes are not unusually long or large in comparison to the cylinder dimensions. This figure expresses the amplitude of the jump. This length divided by the average speed gives the period, and the frequency is the reciprocal of the period. When the load is subject to sudden periodic variations (as it frequently is in machine-tool feeds when the cutting tooth leaves the cut) when friction is low and the mass large, the length of jump may actually be double the amount calculated by this method. If no provision is made for suppression of the jump by controlling the back pressure, it may even be more than double. When the length of jump is sufficiently short and the frequency is sufficiently high, the momentum causes the jumps to run together, and a smooth feed results. This condition is produced by making S low, P low, or V high. Since S and V are generally established by the requirements of the work, the only solution to a problem of jumpy feed is to increase the cylinder bore or to replace the cylinder with a screw feed (see Fig. 17-25).

Positive-displacement Rotary Motors. Any pump, except those which utilize check valves as flow-controlling means, will theoretically operate as a motor. Thus, the ordinary crank and plunger pump cannot be reversed, as the check valves prevent the flow of pressure fluid into it. However, crank and piston motors or hydraulic engines can and have been built.

The suitability of a hydraulic device for use as a motor is affected chiefly by its slip, or leakage, rate and the relationship of its power losses to the generated power, or its mechanical efficiency.

Since the energy input to a motor to produce one revolution is the product of the volume of fluid required to produce one revolution, or the displacement per revolution, and the pressure, while the energy output is the product of the distance traveled by a point at a given radius from the shaft and the force exerted at this point, the mechanical efficiency is

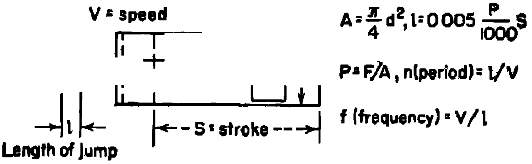

FIG 17-25. Elasticity effects in cylinder feeds.

$$e = 2\pi RF/PV = 2\pi\tau/PV$$

Thus

$$\tau = PVe/2\pi$$

where τ = torque, in -lb = RF
P = pressure, psi
V = displacement per revolution, cu in.
e = mechanical efficiency, per cent

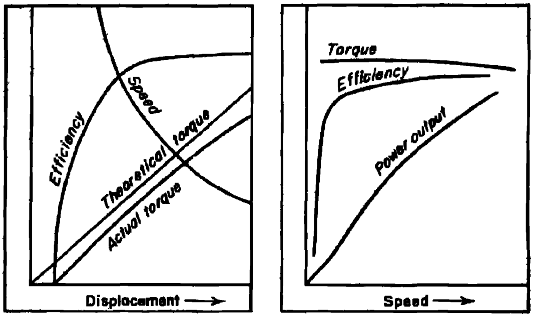
Hydraulic motors are usually applied to drive a machine at a controlled speed or at a controlled torque. They are occasionally used for driving machines in hazardous places, to avoid placing electric motors in the danger area, to provide a suitable means for accelerating very heavy inertia loads, or to provide regenerative dynamic braking of such masses over the entire range to zero speed.

Since hydraulic motors are essentially similar to their corresponding pumps, they can be produced either in the constant-displacement or the variable-displacement types. Furthermore, the loading characteristics of a hydraulic machine limit the pressure to a given value regardless of the speed. Therefore, the torque characteristic of a constant-displacement motor is constant throughout the speed range, and the horsepower characteristic is proportional to the speed. In comparing the performance of this type of motor with other prime movers, it is essential to determine the comparative overload characteristic. Since pressures in a hydraulic system can be easily and accurately controlled, the spread between working loads and overload, which is, in other types of equipment, frequently quite wide to allow for unforeseen peak overloads, may be reduced, since damage to the equipment will not be a result of such overloads. It is therefore essential that the overload and starting characteristics of these motors be checked against a carefully determined requirement of the equipment to be driven.

Speed control of hydraulic motors is usually obtained by controlling the volume of fluid permitted to enter the motor. This may be done either by controlling the stroke of a variable-displacement pump supplying the motor or by means of a flow-control valve in the supply line.

Since speed control is effected by flow control, the effect of slip or internal leakage is to cause the speed to decrease with increasing loads. The effect of slip should be considered over the full working range of speeds. Slip is generally but little affected by speed, and while a variation of a few rpm may be tolerable at 1,000 rpm, it may become a large proportion of the total speed at 50 or 100 rpm and may even cause the drive to stall when full load is applied.

Torque control is achieved either by variation of pressure or by varying the motor displacement. If a variable-displacement motor is used and a constant input volume and pressure maintained, the torque decreases, and the speed increases in approximate proportion as the displacement is reduced. Thus the power output of the motor is maintained approximately constant with changing speed. The approximation lies in the change of efficiency with change of displacement. The efficiency is reduced quite rapidly as the displacement approaches zero. The rate of change of efficiency is a characteristic of the design of each motor but, in general, the speed range obtainable by varying the displacement is strictly limited, probably to between 3:1 and 5:1 (see Fig. 17-26).



Variable displacement motor with constant volume input

Constant displacement motor

FIG. 17-26. Hydraulic motor characteristics.

Crank- and Piston-type Motors. Crank- and piston-type motors are seldom used. They are difficult to construct in multicylinder designs, and thus their torque fluctuates throughout the revolution, and they are large, heavy, and slow-speed machines, thus rather limited in speed range.

Gear-type Motors. Most gear pumps have such low efficiency that they will not run as motors. Except for a few special designs, this type of machine is not suited to operate as a motor. One type is equipped with hydraulic balance ports and is designed for use as a motor. These will operate satisfactorily over a limited range of speeds but at slow speeds become unsteady.

Vane-type Motors. While vane-type motors are well suited for running as motors, most available designs will not start themselves. In most of these units the vanes are held in contact with the vane track by pressure. However, no pressure is generated unless they are initially in contact with the vane track. Centrifugal force is relied upon to cause this initial contact. Therefore a stalled vane motor merely by-passes all pressure past the ends of its vanes. There are, however, designs of vane motors which have auxiliary means for obtaining this initial contact, and these motors have good characteristics.

Piston-type Rotary Motors. At present the preferred type of hydraulic motor is the rotary piston type, both the radial-piston and the axial-piston types being available. These have similar characteristics, much like those of the comparable pump, being capable of satisfactory operation over a wide speed range owing to low slip and high efficiency.

Hydraulic Control Devices. In hydraulic circuits it is necessary to control the direction of flow to the motors, the pressure in any portion of the circuit, the rate of flow to a motor, and to select the portion of the circuit to which pressure is to be directed. Controls can be applied directly to variable-displacement pumps to change direction or amount of flow or to control the pressure. Other controls can be built, either singly or in combination, in valves to be applied in the pipe lines.

Pump Controls. Radial- or axial-piston rotary pumps are capable of being controlled by varying their eccentricity or angularity. Manual or automatic controls can be applied to reverse the direction of flow from the pump, to control the volume of flow from the pump, or to limit and control the pressure generated by the pump. These controls can be furnished to be manually operated, either through screws, cams, levers, etc., or through servomotors powered by hydraulic or other means. They may be power driven or automatic through electric motors or solenoids, hydraulic pilot valves, or automatic pressure regulators.

Pressure-control Valves. Pressure-limiting valves should be applied in every positive-displacement-pump circuit to prevent damage from overpressure. These valves may be of the simple spring-loaded ball or plunger type or more elaborate reverse-flow or piloted type (see Fig. 17-27).

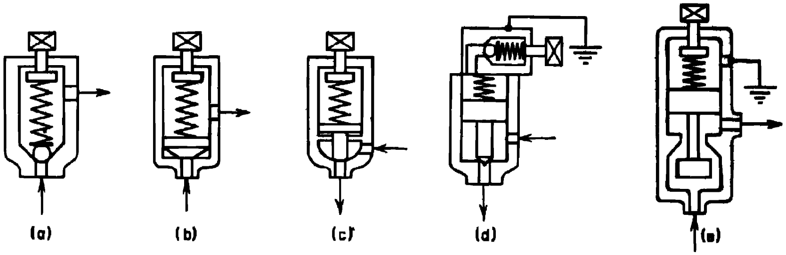


FIG. 17-27. Pressure-control (relief) valves.

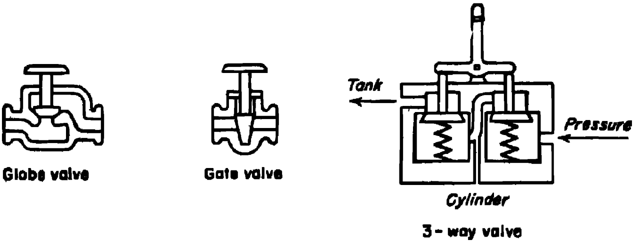
The desirable functions to be obtained from a pressure-control valve are (1) accuracy, the maintaining of uniform pressures for long periods or repeating the same setting uniformly time after time; (2) stability, freedom from whistles, chatter, or other disturbances; (3) freedom from peaks or overshooting under suddenly applied loads; (4) close regulation or uniformity of operation under widely varying flow conditions; (5) wide range of pressure adjustment; and (6) sensitivity in the pressure-adjusting means. Of course, all these are not required for every application. For instance, many valves, once set, are not again adjusted. Also, safety valves which are strictly emergency controls need not have a high degree of stability.

The ball-type relief valve *a* is accurate and dependable for very small flow or for use as a safety valve. However, it is incapable of operation continuously at more than a very small flow or low pressure, as it is unstable and will chatter or whistle, introducing destructive oscillation into the line. The plunger type *b*, having a guided plunger, is more stable as the plunger has only one degree of freedom. A valve of this type is often satisfactory for light or medium duty as a safety valve or for performing occasional control functions. However, it is also inherently unstable and subject to whistle or chatter under unfavorable conditions. The reverse-flow type *c* is stabilized by the addition of a pressure-filled dashpot above the pressure chamber. It has proved accurate and sensitive over wide ranges of flow and pressure and has a relatively low peak with suddenly applied pressure when the dashpot is properly fitted. The pilot-operated type *d* is also stable, accurate, and sensitive. It may be subject to high peaks when the pilot valve is small compared to the flow in the circuit. It can be remotely controlled if desired by separation of main valve and pilot valve, and since the spring on the main plunger is light and since it is assisted by the pilot pressure, the valve is small. This type of valve can be connected to a venting valve if desired. This drains the control chamber and opens the valve to practically free flow.

The valve shown at *e* is a type of pressure-reducing valve. When the downstream pressure is increased above the setting, the plunger restricts the flow to prevent the downstream pressure from rising further. If the controlled flow is to be stopped completely, an artificial bleed or additional relief must be incorporated, as it is unwise to rely upon a single seal to seal tightly under all conditions.

Channel-selecting and Directional-control Valves. Valves that are used to select the part of the circuit to which pressure is to be applied or to reverse the direction of oil flow are of two general types. Seated or poppet-type valves, shown by Fig. 17-28, are those such as globe valves, check valves, or the more complex three- or four-way valves having several plungers operated by a common lever. These valves all make use of the heavy pressure available from screws or cams to seat the disk tightly or use the pressure differential itself to accomplish this seating. These valves seal tightly when the seats are in good condition. However, the disks are subject to erosion or wire drawing if operated in the partially closed position and are affected by particles of foreign matter which may lodge between the seat and disk.



Globe valve

Gate valve

3-way valve

FIG. 17-28. Seated valves.

Spool-type valves (Fig. 17-29) rely upon a good fit and finish to limit the leakage past the fits when closed. In a well-made valve, this leakage can be held to almost negligible amounts for most purposes. Valves of this type are hydrostatically balanced and thus move with little effort. Their movement is small so they can be switched rapidly. They can be built to provide innumerable functions, *e.g.*,

Two-way normally open
Two-way normally closed
Three-way open center
Three-way closed center
Four-way open center
Four-way closed center
Four-way open center with one port blocked
Three- and four-way
Five-way
Six-way, etc.

Spool-type valves can be provided with many operators such as hand levers, return springs, or spring offset, centering springs, hydraulic operation by the main pressure or by pilot pressure, solenoid operation, or operation through servomotors.

A special valve of this type may be called a sequence valve. It is essentially a spool-type two-way valve, spring offset to the closed position and utilizing the line pressure to open it. The operation of a valve of this type is not affected by pressure on the downstream side. Thus it will hold a portion of the circuit in isolation from the pump until a given amount of work has been done as indicated by a rise in pressure. Owing to this pressure rise the plunger opens sufficiently to permit fluid to pass to the isolated section without dropping pressure on the upstream side. When the load on the downstream side exceeds the pressure setting of the valve, the valve will open wide and will have no more effect on the circuit until the pressure again drops.

Flow-control Valves. The rate of flow through a pipe can be controlled by restricting the area through which the pressure can flow (see Fig. 17-30). This can be accomplished by a fixed restriction such as an orifice, by an adjustable restriction as provided by a needle valve or a throttle, or by an automatically self-adjusting valve providing compensation for load variations.

A fixed sharp-edged orifice, if not over half the diameter of a straight pipe in which it is placed, is relatively insensitive to changes in viscosity of the fluid when the rate of flow is above the critical. It does, however, have a varying flow characteristic with changes in the pressure differential. A restriction in the form of a pipe of reduced diameter or an orifice having a length of more than four diameters is affected both by changes in viscosity and pressure differential. Various types of adjustable flow-control devices, ranging from needle valves to V-ported throttle valves, have characteristics ranging between the orifice and the pipe.

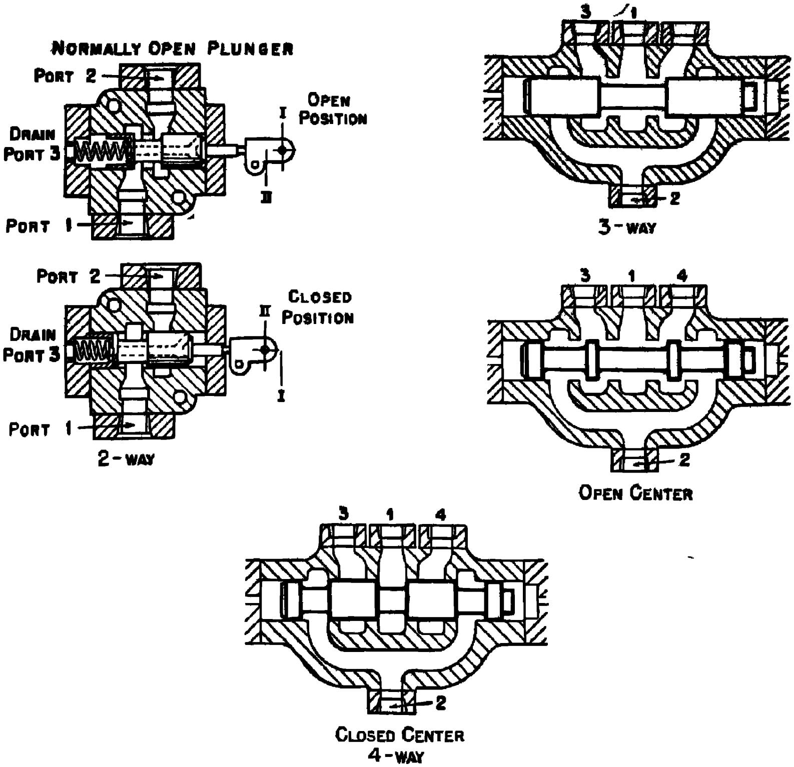


FIG. 17-29 Spool-type valves

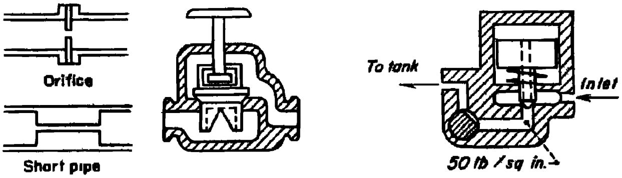

FIG. 17-30. Rate-of-flow controls.

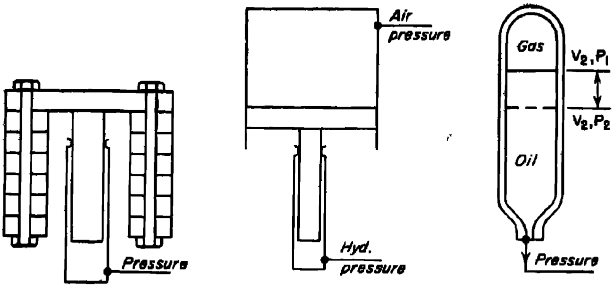
Self-adjusting compensating flow controls consist essentially of an adjustable orifice having a good temperature characteristic, following a pressure-reducing valve.

A valve of this type is placed in the outflow line of the motor so that the orifice will discharge into the reservoir. Thus, since the pressure-reducing valve supplies a constant pressure to the orifice, the flow through the orifice can be regulated and can be independent of temperature and load.

Miscellaneous Controls. A variety of miscellaneous controls such as pressure knockouts, pressure switches, unloading valves, etc., can be obtained. However, these are, generally speaking, modifications of the basic types described. Many special-purpose controls can be designed by combining several basic valves into single units.



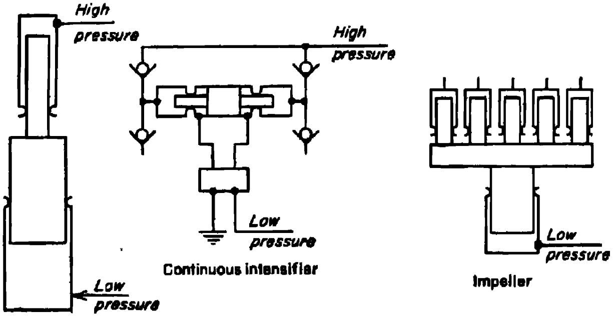
Weighted accumulator

Hydropneumatic accumulator

$$\frac{P_2}{P_1} = \frac{V_1}{P_2}$$

FIG. 17-31. Hydraulic accumulator.

Accumulators and Intensifiers. Only a few of the hydraulic machines now being made use accumulators (see Fig. 17-31). They were originally of great importance since a constant-displacement pump delivers fluid at a constant rate, while the conditions of use dictate its consumption at a variable rate. The accumulator was used to store excess energy during periods when the load is little and to make up the excess requirement when the load is greater than can be obtained from the pump alone.



Continuous intensifier

Impeller

Single stroke intensifier

FIG. 17-32. Hydraulic intensifier.

Accumulators utilize the energy stored in an elevated mass or in a compressed spring or compressed gas to drive a piston or ram which develops pressure on the fluid. Some systems utilize the energy of compressed gas directly upon the surface of the fluid in a confined vessel or through a diaphragm, bladder, or float to provide a storage of fluid under pressure. Accumulators are used chiefly to supply systems that periodically require a great amount of power for short time intervals.

An intensifier is essentially a direct-acting pump delivering high-pressure fluid by the application of low-pressure fluid to connected rams having a differential area (see Fig. 17-32). They are useful to obtain a nonstandard pressure from standard pumps or to provide a stage of high force at slow speed following one of low force at high speed. An occasional use is made of a multiple intensifier (or impeller), consisting of a number of small rams connected to one large ram, to split a single flow into a number of equal, or proportional, flows.

An intensifier can be either a single-stroke type or a continuous automatic pump. If single stroke, it must contain sufficient capacity to perform the required function in one operation and can usually be cut into the circuit by simple valving. If continuous, it is controlled by an automatic valve which causes the intensifier stroke to repeat itself as long as energy is supplied to it.

HYDRAULIC CIRCUITS

While hydraulic principles have been applied to the solution of innumerable problems, the following illustrations will indicate the methods used in the design of a hydraulic circuit. In designing or evaluating any hydraulic circuit, a check list may be of value. The following, while not necessarily complete, will indicate the most important items to consider:

1. Operation.

Will the system operate?

Will it go through a required cycle without stalling or repeating, etc.?

Is the sequence correct?

Is it sufficiently interlocked?

Is there a provision for return fluid where necessary?

Is the pump suction adequate?

Will air be cleared?

Will the pipes drain out during idle periods causing a malfunction on starting?

Is the unit protected against extremes of temperature?

2. Safety and Emergency Operation.

Can the unit be stopped instantly at any time?

How is it started normally?

Can it be damaged by starting after an emergency stop?

How is it recycled?

What "inching" functions are required?

Will any element fall unexpectedly from lack of positive support?

Will creeping take place when idle?

What will happen if a fuse blows?

Will it take care of itself if left unattended?

3. Performance.

Will the equipment do the job?

Has it sufficient force, torque, speed, range, etc.?

Has sufficient allowance been made for lost time?

Has proper allowance been made for off-standard operation, such as operation on 50- or 25-cycle current or the use of standard gear ratios or sheave diameters rather than theoretical values?

Has allowance been made for change in characteristics due to wear?

Has allowance been made for temperature change?

Are all elements and connections of adequate size?

4. Maintenance.

Do the units chosen have the degree of dependability warranted by the importance of their work?

Is their arrangement such that they are accessible for replacement or repair?

Is the oil system protected by adequate filters, coolers, cleaners, breathers, or temperature cutouts?

Is the oil reservoir provided with drainage facilities and a hand hole for cleaning?

Can the oil level be checked conveniently?

Is the equipment "foolproof"?

Is it rugged enough to stand the rough treatment which most industrial equipment sometimes gets?

5. Appearance.

Does the equipment "fit" the job?

Can it be arranged to produce a balanced, harmonious machine?

Are connections and elements simple, and can they be pleasantly arranged?

6. Cost.

Is the over-all cost, including installation, justified?

Pressing Circuits. Pressing is the earliest field of hydraulics and one in which it still excels. It is especially desirable where it is necessary to control the force, length of stroke, or speed of application. The simple press, powered by a pump or an accumulator, has been described. One of the most common problems in this type of equipment is to produce a high-speed approach while the press is idle, then to provide a large force upon the work at a slow speed, required by the nature of the work or to keep the power input within reasonable limits. The two generally used methods are (1) to use auxiliary low pressure for the idle stroke, obtained from a separate pump, a low-pressure accumulator line, or perhaps compressed air, with an automatic switch over to a lower volume high-pressure pump; and (2) the use of gravity or small-size kicker cylinders to cause the platen to approach rapidly with an automatic valve to cut the main cylinder off from connection to the tank to connection to pressure at contact with the work.

Another problem frequently encountered is the obtaining of precision in distance traveled, especially under varying loads. The most accurate and dependable method of accomplishing this is to bring the moving member solidly against a fixed or adjustable positive stop. This generally requires a slowdown before bumping to avoid shock. This is accomplished through operation of pump controls, speed-control valves, or cushions in the cylinder. Other methods are to approach the point of reversal at a speed that will permit precision by quickly reversing a valve; to apply follow-up links or servomotors; or to use cam-operated valves to bring the moving member to rest.

Reciprocating Circuits. Reciprocating circuits comprise the group of planers, grinders, honing machines, transfer conveyors, etc. The reciprocation can be obtained by valving or by reversing the flow from a variable-displacement pump. The main problem is to obtain maximum speed of movement of a heavy mass at uniform speed for the longest possible stroke, then to obtain a smooth shockless reversal in the minimum possible stroke and time. When properly designed, a pilot-controlled valve will provide excellent reversals. However, extreme precision in the point of reversal is not obtained consistently.

Positioning Circuits. Hydraulic cylinders can be equipped with devices to provide accurate positioning of heavy masses against large forces. These systems are illustrated by such systems as ship steering gears or gun-aiming devices. These circuits depend upon differential follow-up devices of many sorts to obtain precision in position. A signal from the controlled element is matched against the signal from the master to set the pump control or control valve to the proper position.

Feed or Speed Controls. Feed control is obtained by adjustment of pump displacement or through flow regulators described under Flow-control Valves. Generally, rapid traverse (obtained from a separate pump) and direction of feed are controlled by auxiliary valving controlled manually, by dogs or cams, or electrically.

Torque Controls. Torque control is utilized in controlling helper drives and sometimes to limit acceleration. Torque control is easily obtained by limiting the pressure applied to the motor by any of the means described under Pressure Controls.

Acceleration Controls. In cases that require a long period of acceleration, it is generally preferable to use an electric pilot motor to change the displacement of a pump at a predetermined rate or to apply a preset pressure, actually a torque control, to limit the rate of acceleration.

LUBRICATION*

BY ALLEN F. BREWER

Technologist, Engineering, Technical, and Research Division, The Texas Company

PETROLEUM CRUDE OIL

There are two basic types of petroleum crude oil from which lubricants are derived, *viz.*, paraffin and naphthene. Formerly, the base was sometimes regarded as a criterion of performance. Today, however, petroleum technology regards methods of refinement as being of more importance than the base or source when it is desired to predict the performance in service of any oil refined therefrom.

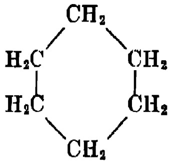
Broadly speaking, base terms are those which have been adopted by the chemist to indicate the nature of the hydrocarbons which predominate in the make-up of an oil. Petroleum research has designated four classifications, *viz.*,

1. Naphthenes
2. Paraffins
3. Asphaltenes
4. Aromatics

All are present in virtually any type of crude petroleum. Usually some one group predominates, according to the geological locality from which the oil has been obtained. For example, oils produced from Pennsylvania, New York, and West Virginia fields contain largely paraffin and naphthenic hydrocarbons. In the mid-continent area, the mixed-base or naphthene-paraffin-asphaltic hydrocarbons predominate. Ohio, Kentucky, and Indiana fields produce such oils, as do also the Kansas, Oklahoma, and North Texas areas. The Gulf coast and California crudes in turn consist of naphthene, asphaltene-paraffin combinations, with the former predominating.

Regardless of these combinations, complex compounds of carbon and hydrogen are involved, in percentages ranging from 83 to 87 for carbon and from 11 to 14 for hydrogen. Some sulfur, oxygen, and nitrogen may also be present according to the source of the crude, but they will usually be considerably below 5 per cent.

In the make-up of the four classifications the so-called saturated and unsaturated hydrocarbons are of primary concern. The former predominate as naphthenes and paraffins. The naphthenes correspond to the formula C_nH_{2n}, being known as closed-ring groups, according to the number of carbon atoms. A typical naphthene is cyclohexane.



Some of the better known paraffin derivatives of petroleum are

Methane, CH_4
Ethane, C_2H_6
Propane, C_3H_8
Butane, C_4H_{10}
Heptane, C_7H_{16}
Octane, C_8H_{18}

---

* Superior numbers refer to specific references listed at the end of this subsection.

Among the better known aromatics are

Benzene, C_6H_6
Toluene, $C_6H_5CH_3$

THE REFINING PROCEDURE

The segregation of crudes has become a vital part of refinery operation, for subsequent refinery processing must be planned according to the type of refined products that can be economically produced. By controlled distillation a variety of light products can be fractionated from the naphtha, gasoline, and kerosene stocks through the lighter lubricating-oil range to those heavier distilled oils which are so advantageous for diesel-engine lubrication.

Distillation, however, does not remove all the objectionable unsaturates or readily oxidized hydrocarbons which are present in virtually all crudes. They must be further treated with acids, alkalies, and solvents. Then, to improve the low-temperature characteristics where necessary, the lubricating stock is subjected to dewaxing—removal of those paraffins which are solids at temperatures of 90°F or higher in the pure state.

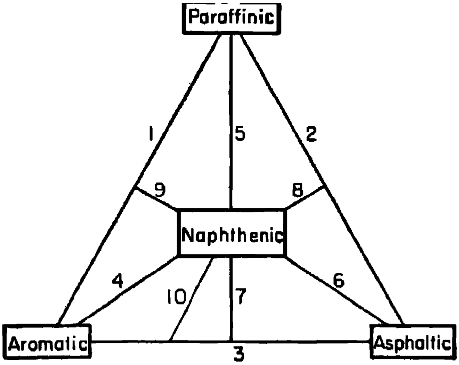


FIG. 18-1.

The object throughout is to produce a series of refined products, regardless of base, which will be free from gum-forming constituents, resistant to oxidation, capable of flowing freely at low temperatures, and heat resisting at high temperatures. Very often the knowledge of how raw stocks will respond to the necessary refining procedure is more important than the source or basic hydrocarbon make-up of the crude. The finished products will be most stable if composed of the so-called saturated paraffin or naphthene hydrocarbons.

Gruse[1] has presented a most enlightening analysis of the arrangement of these hydrocarbon components in petroleum oils. Based on the premise that "all crude oils are mixtures of various types of hydrocarbons," he shows, as indicated in Fig. 18-1, that the naphthenes are of chief importance as they are present in all crude oils and furthermore that the paraffins are almost as widely distributed. To some extent this would discount the preference that has developed for oils by base or source in favor of a more intelligent consideration of their method of refinement for the purpose involved. He further states:

> The four main constituents can be placed on a diagram as shown by Fig. 18-1, and mixtures of the constituents can be expressed by lines joining the constituents. For example, line 1 describes a mixture of paraffins and aromatics; line 2, a mixture of paraffins and asphalt; and line 3, a mixture of aromatics and asphalt; no point on these represents crude oil. Lines 4, 5, and 6 represent mixtures of naphthenes with aromatics, paraffins, and asphalts, respectively; points on these lines will represent real crudes. Line 7 repre-

sents a mixture of naphthenes with aromatics and asphaltic compounds, and lines 8 and 9 have similar obvious significance. Line 10 represents, as does line 7, a mixture of naphthenes with aromatics and asphalt, but a mixture in which the aromatics predominate over the asphaltic constituents; crudes on line 10 would be more aromatic than those on line 7.

This diagram can be read one step further to learn that line 5 denotes a so-called Pennsylvania oil; that line 6 shows a Gulf coast stock; line 8, an oil from the mid-continent area. Thus, naphthenes occur in all, with the paraffins and aromatic or asphaltic compounds included in varying amounts according to their source.

It is usually most important to control the aromatic and asphaltic content in oils refined for lubricating purposes. This is accomplished by proper choice of the crude stock and the use of methods of solvent treatment, especially where the resultant oils are to be used for automotive or diesel engines, the steam turbine, or refrigerating compressor.

The paraffin component is not so readily controlled unless improved methods of dewaxing are employed. It was once thought that the paraffin hydrocarbons were of more importance than they really are, perhaps owing to the fact that the earlier lubricating stocks were obtained from the predominatingly paraffin fields. Today selected methods of solvent refining can be applied to control the ultimate tests to a remarkable degree, in many cases giving a naphthene-base oil many of the physical characteristics of a paraffin.

In turn, by solvent dewaxing, the pour test of paraffin oil can be made comparable with that of a naphthene-base product. For internal-combustion-engine service, the method of refinement is highly important. It is especially essential to control the carbon-residue content and the unsaturate content. The former may be the cause of objectionable deposits which later may be agglomerated by gummy residues, resulting from oxidation of the unsaturates.

TESTS TO DETERMINE LUBRICATING-OIL CHARACTERISTICS

Effective lubrication is attainable by considering the controlling factors and by coordinating these factors as far as is possible. Lubrication begins with the selection of lubricants. In the process of coordination the characteristics are studied with due consideration of the machinery to be lubricated, the conditions under which the lubricants must function, and the means by which they are circulated or applied.

To select lubricants most intelligently, it is necessary to be informed on their physical characteristics and the significance each characteristic bears to the service involved. Laboratory tests are employed to determine these characteristics and also to obtain some idea of how an oil may perform in service.

Gravity. Gravity is of significance as a measure of the relative unit weight of certain petroleum products. It is normally of no value as an index of lubricating ability. In fact, the gravity, as indicated by the Baumé or API scales, is of use only as an indication of the crude base from which such products have been derived. Those from paraffin-base crudes will show a lighter gravity than those from naphthene crudes.

Viscosity. Viscosity is that property possessed by all liquids which serves as a measure of their ability to flow and an indication of the extent to which internal or fluid friction must be considered. The heavier an oil, the higher will be its viscosity, owing to the resistance which the particles or molecules will offer to one another when in sliding contact at a given temperature.

The meaning of viscosity and the means by which it is customarily determined must be understood in order to conform to the lubrication recommendations of machinery builders and attain most effective lubrication with minimum fluid friction. Use of an oil of too low a viscosity or one too light in body may lead to metal-to-metal contact and wear if the oil film is too thin to carry the prevailing loads. Use of too heavy an oil may lead to power losses due to the inherent sluggishness of such an oil.

Viscosity is measured in terms of time by noting the number of seconds required for a certain quantity of oil to flow through an orifice of standardized size at a certain definite temperature. The ASTM has adopted the Saybolt Universal viscosimeter for commercial purpose, with 60 cc as the usual volume of oil involved. Lubricating

* Courtesy of *Lubrication;* The Texas Company.

NOTE: The difficulty of obtaining accurate Saybolt Universal values for viscosities lower than 45 SSU at 210°F is so great that the viscosity-index table is not extended below that limit. The accuracy of the viscosity index may be increased by the use of the kinematic viscosimeter at 210°F for oils having viscosities between 40 and 75 SSU at 210°F since the conversion of kinematic viscosity in this range at 210°F to Saybolt viscosity is more reliable than the actual Saybolt determination. To show which viscosity-index values are in this critical range, dotted lines have been used to set it apart from the rest of the table.

oils for plant service are generally measured at 100 and/or 210°F. The viscosity of lighter oils (turbine grade, for example) is measured at 100°F. Heavier products such as steam-cylinder oils or gear lubricants are tested at 210°F. Accordingly, reference to an oil as being of 300 or 500 SSU viscosity at 100°F means that 300 or 500 sec, respectively, would be required for the standard volume to flow through the

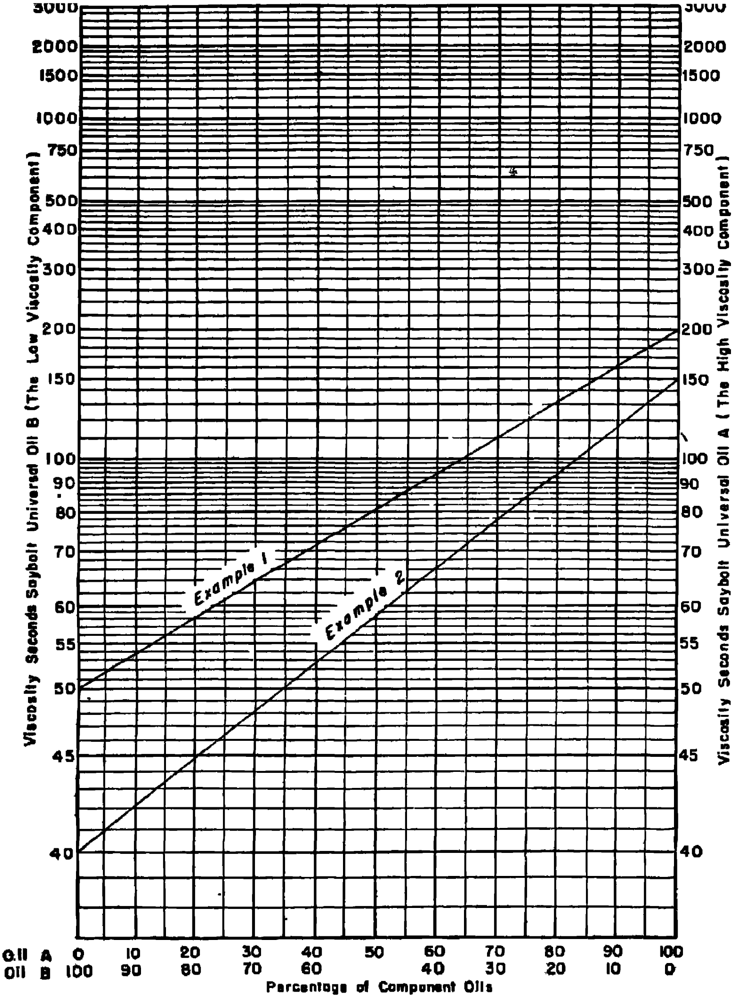

FIG. 18-2. Viscosity blending chart. (*Courtesy of Lubrication, The Texas Company.*)

Saybolt Universal viscosimeter at that temperature. A viscosity blending chart is shown by Fig. 18-2 with instructions for its use given in Fig. 18-2*a*. Data for estimating viscosity index is shown in Table 18-1.

Flash Point. The flash point of an oil is that temperature at which inflammable vapors will be given off to a sufficient degree to ignite momentarily when exposed to a naked flame. Flash point is of importance when an oil may have to be exposed to high temperatures, *e.g.*, when considering whether an adequate lubricating film will be maintained on engine cylinder walls without undue loss by vaporization. Lubricating oils for internal-combustion engines will have a flash-point range of from 325 to 425°F, according to the base of the oil and its viscosity. Naphthenic-base oils will show a somewhat lower flash point than those of paraffin base of the same viscosity. Flash point also increases with the viscosity of oils from the same source. Accordingly, a 500-viscosity product will in general show a somewhat higher flash point than a 200- or 300-viscosity oil of the same base.

The flash point always should be sufficiently high to ensure that there will not be any hazard under storage due to vaporization of the more highly volatile constituents. Good quality lubricating oils of reputable manufacture will adequately meet this requirement since all will range above 325°F, which in turn is far above any extreme temperature that might occur under storage.

HOW TO USE THE VISCOSITY BLENDING CHART

In order to adapt the viscosity-temperature chart as a blending guide, we have used that portion of the chart between 0 and 100°F, covering a viscosity range of 37 to 3,000—the range ordinarily encountered. Let the left vertical represent 100 per cent of the lighter oil, or Oil B. Let the right vertical, represent 100 per cent of the heavier oil, or Oil A. By plotting the known viscosities of any two oils at the same temperature on these respective verticals and connecting them by a straight line, points along this connecting diagonal show the viscosities at the given temperature according to the proportion of the respective oils in the blend.

Example 1. How much oil of 50 SSU at 100°F (Oil B) must be blended with a 200 SSU at 100°F (Oil A) to give a 100 second viscosity oil?

Draw a line between the 50 and 200 viscosity points on the respective zero lines. Note where this line crosses the 100 viscosity horizontal. The answer is 36 per cent of 50 viscosity oil (Oil B) and 64 per cent of 200 viscosity oil (Oil A).

Example 2. What is the viscosity of a blend of 20 per cent of a 40 SSU at 100°F oil (Oil B), and 80 per cent of a 150 SSU at 100°F oil (Oil A)?

Draw a line connecting 40 viscosity on the Oil B line, and 150 viscosity on the Oil A line. This line crosses the 80 per cent line (Oil A) at 94, indicating 94 SSU at 100°F, to be the viscosity of the desired blend.

FIG. 18-2*a*.

It is comparatively easy to make the flash test with the proper kind of apparatus. However, it may be materially influenced by such factors as the shape and size of the receptacle used, the rate of heating, the presence of air currents, the atmospheric pressure, the size of the flame used to make the test, and the distance this flame is held above the surface of the oil in the test cup.

The flash point has no relation to the spontaneous-ignition point; this will be very much higher than the flash point.

Fire Point. The fire point is also a temperature measurement. This characteristic is of interest primarily because of its connection with the flash point.

The fire point is determined by increasing the temperature of the oil in the flash-testing apparatus until the resultant vapors ignite and burn continuously when the test flame is introduced. The temperature of the oil at which this takes place is regarded as the "fire point" of the lubricant under test.

Pour Test. The pour test is a measure of the lowest temperature at which an oil will pour or flow under the conditions of the ASTM procedure. This test is of interest to plant operators who must handle oils under relatively cold conditions, especially where intermittent running may be necessary. In an engine operating at low atmospheric temperatures and equipped with mechanical force-feed lubricators, the pour test of the oil used would be of much importance. Any tendency towards congealment in the lubricator or in the crankcase of an enclosed engine (especially when shut down) might cause the pumps to become inoperative, with the result that lack of lubrication, scored cylinders, and burned-out bearings might readily occur. It is perfectly practicable to obtain lubricants of the highest quality which will show a pour test of 0°F or slightly above, according to their viscosity. Naphthenic-base oils in general show a lower pour test over the same viscosity range than paraffin-base products unless these latter have been subjected to special dewaxing treatment.

Carbon Residue. The development of an excess of carbon residue will be detrimental to the attainment of maximum efficiency in internal-combustion engines owing to the tendency which this material has to deposit on piston heads, in combustion chambers, on valve seats, and around and under the rings. Free carbon is chiefly the result of breaking down or decomposition of lubricating oil exposed to the combustion process.

All engine deposits are not always free carbon, however, although this latter element may be most obvious when such accumulations have to be cleaned out. Dirty air is a prevalent cause of carbonaceous deposits, for finely divided particles of dust will combine with carbon residues, particularly if they are of a gummy nature.

Means should be provided, therefore, to reduce the extent of such deposits before they have a chance to form. As far as the lubricant is concerned, this is best done by selecting oils that show low carbon-residue tests and then using such oils (in engine cylinders especially) in as nearly the right amounts as possible to reduce the volume subjected to the possible decomposing effects of the operating temperatures. From a mechanical viewpoint the best preventive (in engine and compressor service) is to use an air cleaner of proved ability and thereby remove the dust particles before they have a chance to combine with any free carbon to cause gummy residual matter.

Emulsification. Emulsification is used in connection with the tendency of an oil to go into such intimate mixture with water as to form a definite emulsion. It applies especially to liquids that are insoluble or only slightly soluble in each other, the mixture being so stable and the liquids so mutually held in suspension that natural separation takes place at a very slow rate. This rate of separation can be retarded by addition of certain fixed or fatty oils to straight mineral oils, as is customary with lubricants for steam cylinders where saturated steam is used. In this way emulsification is accelerated and the resultant emulsion rendered more permanent.

Emulsification is of advantage wherever a lubricating oil must be used in the presence of moisture, especially if sludge formation need not be seriously regarded. Otherwise emulsification must be guarded against, for it is normally a prelude to oxidation and permanent sludge formation. Sludge must always be seriously considered in connection with oil circulating systems or wherever an accumulation of nonlubricating gummy matter may interfere with complete circulation of the oil.

Demulsibility. Whereas emulsification is a measure of the tendency of an oil to go into more or less permanent mixture with water, demulsibility is a measure of the readiness with which separation will take place. Demulsibility is important in any turbine or diesel operation where the oil must be continuously circulated through comparatively small oil piping and through low bearing clearances. Of equal importance, however, is the matter of preventing entry of water through leaky cooling-water connections or abnormal condensation and providing means for water separation and removal from the lubricating system. The conventional oil purifier or filter will normally perform in a satisfactory manner.

The demulsibility of an oil will depend upon the degree of refinement of the oil. The more highly or accurately refined an oil, the better will it separate from water.

This holds true primarily for the lower viscosity range of lubricants, for in oils of the same degree of refinement, as the body is increased, the readiness with which an oil will separate from water will be proportionately reduced.

Sulfur. Sulfur is objectionable in a diesel-engine lubricating oil or fuel only when it is in such form as to be corrosive. In a diesel fuel, sulfur content up to 2.0 per cent is allowable in large slow-speed engines. Sulfur becomes most serious after combustion when there is possibility of contact with water, thus causing sulfurous and sulfuric acids which are corrosive.

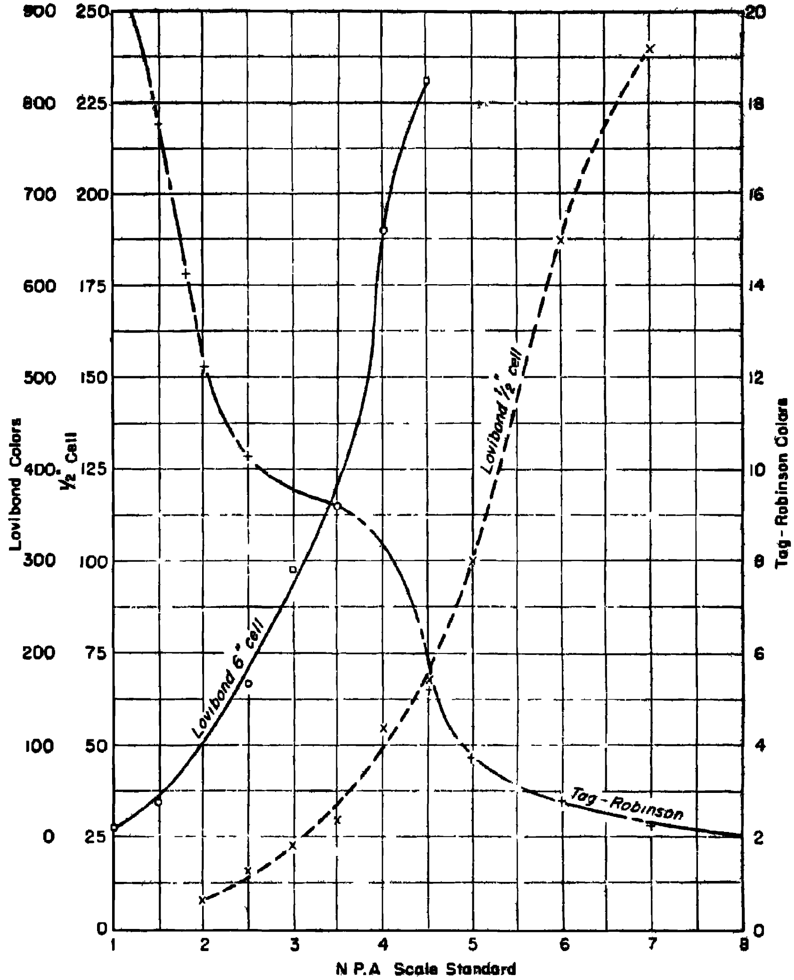

Fig. 18-3. Color conversion chart.

In determining the sulfur content of petroleum products, oxidation and analysis of the oxidized materials are customary. Sulfur in diesel fuels is often regarded as more serious than it really is. Normally, sulfur compounds in petroleum fuel oils have a high Btu value and are completely burned. Sulfur dioxide, as the product of such combustion, is noncorrosive unless there is possibility of contact with condensed water.

Saponification Number. Saponification is a chemical reaction involving the action of an alkali upon a fat or fatty acid, the resultant combination being termed a soap. Saponification will not occur in a well-refined petroleum oil except where fatty acids may result owing to oxidation. However, the principle of saponification is the basis for the manufacture of greases by which a fatty oil or acid is treated with caustic soda or potash or other alkaline metal compounds.

The tendency an oil may have to saponify is determined by measuring the equivalent amount of caustic potash necessary to react with or saponify 1 gram of the oil under test. In terms of milligrams of caustic, the resultant figure is called the saponification number of the oil.

Any lubricating oil for internal-combustion-engine cylinder or crankcase lubrication should show as low a saponification number as possible. When dealing with a compounded oil, however, the presence of a small amount of fatty oil may affect the saponification number proportionally. Some authorities also hold that this increase in the tendency towards saponification will have a like effect upon the tendency towards oxidation and gum formation. They urge that the rate of increase in the saponification number of the used oil be closely watched.

Acidity and Neutralization Number. Organic acids may be present in fatty oils as well as in petroleum or straight mineral oils. The nature of these acids will differ, however, according to their carbon content. In petroleum oils such acids are normally weak and noncorrosive. They should be minimum in a well-refined new oil, but even the best of such oils will show a slight increase in acidity with usage under oxidizing conditions involving heat, moisture, and air. Their noncorrosive nature eliminates one cause for worry. However with increase in acidity, the tendency towards sludge formation will be increased.

Acidity is measured by neutralization; there is, therefore, a direct relationship between the two terms. The "neutralization number," as an index of the acidity, is taken as the weight in milligrams of potassium hydroxide which is necessary to neutralize 1 gram of the oil under test. Since mineral acidity may be more serious from a corrosive angle than organic acidity, the former must be nil. Fortunately, this can also be predetermined by neutralization. Usually the determination of mineral acidity is made only on used oils to determine freedom from or extent of contamination. Unused oils should always be free from any mineral acidity and are so refined.

The Value of Color. Color is simply a visual measure of refinement; it is a function of the refining process; it does not assure the adaptability of any finished petroleum product for a specific use. It can be determined in a number of ways (see Fig. 18-3 for conversion).

The color of refined petroleum lubricating oils may vary all the way from a virtual water white to a deep red or green. Spindle oils are usually of a pale straw hue, although this is by no means a measure of the lubricating qualities. The lighter the color, the better the possibility of absence of undesirable foreign material. However, the color has no bearing upon the ultimate usage.

The color of a petroleum distillate is also to some extent indicative of the viscosity; lighter bodied oils are more nearly of the yellow-straw tinge; the heavier the body, the darker the oil for the same degree of refinement.

GREASES

Base. The term base is indicative of the type of soap used in the manufacture of a grease. In plant service the chief concern is with products of soda or lime base or the mixed-base products designed primarily for ball or roller bearings. There are also specialty greases containing other metallic soaps such as aluminum, lithium, barium, or lead, which are intended for more specific usage.

The Dropping Point. Heat causes a grease to soften. The temperature at which it passes from the semisolid to a so-called liquid state is called the dropping point. It can be defined as the temperature at which a drop of grease disengages itself from the remainder.

In the ASTM test (method D-566-42), the temperature of a grease sample contained in a cup is raised at a standard rate. When the grease has become sufficiently fluid so that one drop falls through a hole in the bottom of the cup, the temperature is noted, and this temperature is termed the dropping point of the grease. Since semifluid greases extrude from the cup at room temperature, this test is not applicable to them, nor is there a standard method for determining their dropping point. Dropping point is controlled by the percentage of soap present, the nature of the fatty oil, and the type of alkali. This latter will usually have the most pronounced effect, greases of soda base or soda-lime base having a higher dropping point than those of straight lime base.

The dropping point of a grease does not indicate the maximum temperature at which it can be used. Ordinary cup greases, for example, in which the oil and soap are held together or stabilized by means of water, have dropping points around 200 to 225°F, yet very often they will not stand up at temperatures continuously above about 175°F since continued subjection to heat of even this intensity causes vaporization of the water, and eventually the grease separates, and soap and oil result. Yet, there are some greases that can be used for short periods of time even above their dropping points provided the bearing housing is sufficiently tight to prevent leakage of the fluid grease.

The dropping point of a grease should be used primarily as an indication of uniformity of manufacture and as a means of identifying greases. The best way to determine high-temperature performance of a grease is to test it in the laboratory under simulated field conditions or by actual service in the units it is designed to lubricate.

Penetration. Penetration is a measure of the consistency and texture of a grease. Numerical measurement of this property is made by allowing a cone-shaped weight of standardized size to drop into a sample of the product at a certain definite temperature. The distance to which this cone penetrates in hundredths of a centimeter is termed the penetration of the grease under test. Obviously, the harder the grease, the lower will be the penetration or the harder the consistency.

PLAIN BEARING DESIGN AND CONSTRUCTION

Alignment. Alignment is a most important factor in the maintenance of efficient plain bearing operation. Any misalignment will immediately lead to abnormal wear, varying in intensity according to what might be termed the angle of error. Under such a condition the shaft will not bear uniformly over the bearing surface but at the ends with abnormal pressure. This may readily lead to excessive wear at these points, overheating, and even wiping of the bearing metal.

The longer the bearing with respect to the diameter, the greater may this wear become under even very slight conditions of misalignment. In view of this, bearing designers endeavor to reduce the length wherever possible and approach a length-to-diameter (LD) ratio of around 2:1, or even 1:1 in some cases. This becomes especially beneficial on power-transmission equipment.

Oil Grooving. When soft metals predominated in bearing design, oil grooving was a generally accepted procedure. This still holds true, for proper grooving is a definite assistant to lubrication of the tin- or lead-base bearing metals.

With harder bearing alloys, mirror finishes, increased machine speeds, and perfection of flood and pressure oiling systems, oil grooving is regarded as less important. In fact, in automotive- and aviation-engine design, rod and pin bearings may carry no grooving at all on the theory that development of the oil film under constant pressure will maintain this film in conjunction with the natural pumping action which is developed at high speeds. Furthermore, elimination of grooving increases the effective bearing area, permitting reduction of over-all bearing dimensions.

Oil grooves, where necessary, are cut in the low-pressure surfaces of the bearing to aid in developing complete circulation of oil and maintenance of a sufficiently protective film at the high-pressure area. They constitute a series of depressions in the bearing surface, connected or so located with respect to each other and the point of maximum bearing pressure as to ensure not only complete and ready distribution of lubricant throughout the bearing clearance but also a pathway for collection and subsequent removal of any nonlubricating material which might otherwise interfere with free flow of the oil film (see Fig. 18-4).

Not infrequently, too little importance is attached to oil grooving in bearings where it should be applied. Some engineers have even felt that it was necessary only to drill an oil hole or two and that the film would spread by some means. This is literally true in the precision bearing designed for circulated flood lubrication, but it is not to be depended upon in rough-service bearings where an oil cup or compression grease cup may be the means of lubrication. The rotating shaft always develops some pumping action to draw lubricant into the clearance, but unless wedge formation is facilitated by chamfering at the point of oil inlet, this action may be very slight. Then boundary lubrication is approached. Hot-running bearings with increase in power consumption and ultimate wiping of the bearing metal are indications of such a condition.

Fig. 18-4. Typical bearing grooving for marine engines.

Bearing oil grooves should not just be cut to a pattern to suit the individual. Some definite designs have been applied so successfully in practice as to render them virtually standard. Then they can best serve as a means of distributing lubricant lengthwise along the bearing so that the clearance is uniformly filled. The lubricating film is maintained by rotation or sliding of the moving element developing the necessary pumping action. The groove is merely an inlet receptacle for receiving and distributing the lubricant. Where properly designed, the groove can also aid in keeping lubricant within the clearance, preventing excessive leakage at the ends of the bearing. Such a design facilitates circulation of the oil alternately from the center to the outer ends of the bearing and back again. How intricate to make the grooving design would depend upon the means of lubrication. With periodic lubrication, involving sight or drip-feed oil cups, oil grooving and oil retention are more important than where flood lubrication and oil circulation are available.

Planning the Grooves. Oil grooving is most effectual where it is of comparatively simple design and devoid of sharp curves. The more usual designs, as shown by Fig. 18-4, have been developed through practical experience and probably many thousands of hours in engine, compressor, or shaft service. Any or all might function effectively under similar operating conditions provided the lubricating system is dependable. The all-important factor is to develop lubrication to such a degree that friction and power consumption will be reduced to the minimum. The means employed is more or less secondary, although the effective bearing area must not be reduced by too extensive grooving. Grooving should be applied only to those bearing areas which are in the low-pressure zone. In a two-part bearing this will mean that only the top should be grooved. In a four-part bearing the segments to consider would depend upon the direction of rotation of the journal or shaft. Normally the bottom part should be plain or ungrooved.

The purpose is to be in accord with the theory of lubrication which dictates that oil must flow from a low-pressure area to a zone of higher pressure. Grooving of the high-pressure zone might result in the grooves becoming runways to lead oil away from the clearance. Ultimately starved lubrication and actual metallic contact might occur, especially under high load conditions. Oil leakage at bearing ends is often an indication of faulty grooving or grooving extending into the high-pressure area, especially if bearing temperatures increase at the same time. No bearing should be cut away or have the continuity of its surface altered by grooves within 30 deg either way of the point of maximum pressure; otherwise uniformity in the oil film may be impaired.

Cutting or Formation. Having decided upon the bearing area which should be grooved and the types of grooves to use, it is then advisable to make a rough calculation of the dimensions. These will depend upon the diameter of the shaft or journal which is to be carried by the bearing.

The width of a groove is calculated by multiplying the diameter in inches by 0.01 and adding 0.10 in. as a factor of safety.

The depth of the groove is taken as one-half the calculated width.

An oil groove should never be extended too close to the end of a bearing surface, otherwise a channel might be provided which would allow the oil to escape from the bearing clearance to be prematurely lost by drip or leakage. The approximate distance a groove should be from the bearing edge varies according to the diameter, as shown in Table 18-2.

Bearing-metal Thickness. It is obvious that the bearing metal should always be thick enough to allow for the calculated depth of groove without danger of cutting through to the bearing shell. Therefore, it is advisable to note the approximate thickness of bearing metal available before the grooves are cut or the edges chamfered.

It must be realized, when planning a system of oil grooving and calculating the dimensions, that the available bearing area is reduced by these grooves. Under normal conditions, where they are cut in the top half or low-pressure area, actual metal-to-metal contact may not be as likely as in the high-pressure area where the load is carried. But as some pressure is carried over the entire bearing, especially under higher speed conditions, even the low-pressure area should not be reduced any more than necessary by excessive grooving.

Table 18-2.

Bearing diam, in.	*Distance of oil groove from either end, in.*
1¾ or less	¼ min
1¾–2	⅜
2–6	½
6 and larger	1

The actual cutting of an oil groove must be done with the utmost care in order that the finished groove may conform as closely as possible with the calculated dimensions and the intended location with respect to the curvature and length of the bearing. Uneven cutting or irregular edges may lead to clogging if nonlubricating material gains entry. More or less nonlubricating solid foreign matter such as dirt or metallic particles will be present in almost any oil after service for any length of time. Furthermore, if higher operating temperatures prevail, certain types of lubricants may have a tendency to form gummy or carbonlike deposits of oxidized oil or separated soap from grease. As material of this nature is also more or less inert, it will reduce the circulating ability of an oil and accumulate at high spots in the oil grooves to serve as a dam and further impede free and complete circulation of the lubricant. Once begun, accumulation of nonlubricating deposits is often cumulative to such an extent that ultimately bearing failure will result through starved lubrication at the pressure area.

Oil grooves can be cut by hand or by machine. With hand cutting there may be possibility of some variation from the calculated dimensions, although the fineness of the work will depend upon the skill of the mechanic and the care in handling the cutting tools. Rough surfaces must be eliminated regardless of the method of cutting, for as already indicated, rough spots will not only impede free oil circulation, but they may also act as catchalls for nonlubricating foreign matter.

Roughness in an oil groove may be indicated by loose particles of bearing metal. If adjacent to the main surface of the bearing, the occurrence of metal-to-metal contact might lead to breaking or chipping off of certain of these metallic particles, causing contamination of the lubricant and possible scoring of the shaft or bearing surface, especially where bearing alloys containing a considerable amount of harder metals are involved.

CIRCULATING OILING SYSTEMS

Circulation of fluid oils under uniform pressure conditions is helpful in reducing operating temperatures through the cooling effect of an excess of fresh cool oil. Heat is one of the contributing causes of oil oxidation, especially if the oil is exposed to air and metallic particles. Oxidation is evidenced by sludge accumulations and increase in the neutralization number of the oil by the formation of organic acids.

Under comparatively low speeds, the peripheral speed, as it affects the ability of the oil to free itself from entrained water, is important. This becomes more apparent with heavier oils as these (after usage) do not free themselves from water so readily as do light oils. Viscosity is also a factor as it may be related to the pressure developed by the circulating system, the pressure exerted upon the bearings, and the facilities for reconditioning. One of the premises on which the theory of lubrication is based is that oil viscosity can be reduced as the speed of the rotating parts is increased. Therefore, from a speed viewpoint only, it would be right to presume that lighter bodied lubricating oils should be used in high-speed circulating systems. Certainly they would serve as more effective bearing coolants in removing surface heat by conduction. But the matter of bearing pressure also must be considered on many modern machines. This has increased with increase in speed, and heavier loads need greater body in the lubricating film. This requires prior consideration of load-carrying capacity over heat-transfer ability, for the latter can be controlled by increasing the volume of oil circulated through the system.

As a result, a variety of combinations has been developed ranging in simplicity from the unit type of gravity-feed system to those multiple-power devices whereby an entire series of sleeve-type or roller bearings can be served by one oil under the same constant pressure.

The latter has been accepted as a most efficient method of bearing and gear lubrication with the perfection of the sleeve-type roll-neck bearing, the heavy-duty roller bearing, and the oiltight gear housing. The principle is to circulate cool, clean oil under uniform pressures from a central reservoir to bearings and drive gears to provide proper lubrication and to remove heat from the friction surfaces. This keeps the operating temperatures within reasonable limits.

Pressure Oiling by Gravity. In the operation of a gravity system, the supply pump delivers oil from the settling or sump tank to an overhead supply tank which is mounted high enough to give ample pressure to the gears and bearings. An oil overflow line from the overhead tank to the sump tank returns all surplus oil delivered by the pump. From this overhead tank a supply line, through an assembly of lines, delivers oil by gravity to the various points of lubrication. The oil then returns by gravity to the sump tank located below the operating floor.

Gravity circulation reduces the intricacy in construction and the necessity for costly automatic controls, but it is limited in regard to available pressure owing to plant conditions. Where this pressure is low, it may influence the choice of the viscosity of the oil.

Full-pressure Lubrication. With full-pressure lubrication, a supply pump delivers oil at a predetermined pressure from the settling tank to a pressure tank in which an air cushion is provided at the top. Usually two pumps are provided, one of which may serve as a spare. This latter cuts in automatically by means of electrically operated pressure switches when the pressure in the pressure tank drops below a predetermined minimum owing to failure of the operating pump or whenever the latter is unable to maintain the desired pressure. If both pumps fail or are unable to maintain sufficient pressure, a third pressure switch, which is set just below the minimum operating pressure required, sounds an alarm.

The expansive action of the air cushion in the pressure tank forces the oil through the main supply line and the numerous branch lines. These are equipped with orifice plates or valves to provide each bearing or gear unit with its proper share of lubricant. Frequently each of the various points of lubrication is equipped with a pressure switch and light signal to warn the operator should the oil flow be interrupted. The return oil from the gears or bearings flows back to the settling tank by gravity; here it is subjected to filtration and purification to fit it for recirculation.

Pressure Control. Oil pressure in a pressure lubricating system must be carefully controlled within the limits established by the machine designer. Usually from 5 to 15 lb will prevail. Excessive increase in the pressure under which oil is delivered to bearings may cause seal leakage. Then loss of oil and possible entry of water would more than offset the cooling benefits of the increased volume of oil delivered. Most effectual lubrication in a circulating system results when the oil is kept as free as possible from water.

Essential Equipment.* *Oil Cooler.* An oil cooler of ample size is provided to lower the temperature of the oil leaving the pressure tank. For best results an ample supply of cooling water must be provided for the cooler, and the latter must be kept clean. Thermometers inserted in the oil lines entering and leaving the cooler serve as indicators of the efficiency of the cooler.

Oil Filters. Pressure filters installed between the pumps and the pressure tank remove any foreign matter that might remain in the oil drawn from the settling tank. Filters of the latest design have a self-cleaning feature which requires very infrequent dismantling for the removal of the collected foreign matter from the filtering medium.

Centrifugal Purifiers. Many circulating systems will also include one or more centrifuges which are usually operated intermittently for an hour or so each day. Where large quantities of water may get into the system, however, the centrifuges are sometimes run continuously until the source of the water is located and the leak corrected.

Settling Tanks. With the possible exception of the circulating pumps, the settling tanks are the most useful and necessary features of the circulating system. Where there is any chance of considerable water getting into the system, it is advisable to install two settling tanks so that, when the oil in one tank shows signs of emulsification, the contents can be taken out of service for reconditioning. This is done by heating the oil, by means of steam coils located in the bottom of the tank, to a temperature sufficient to reduce the viscosity and enable the entrained water to settle to the bottom whence it can be drawn off through the drain valves.

A well-designed settling tank will have several large cleanout valves located along the front and as near the bottom as possible. It is also desirable to slope the bottom of the tank toward the front. Then by periodically opening the drain valves, the accumulation of water and sludge in the tank can be held to a minimum. Floating suctions are also often installed to allow the pumps to take the cleanest oil which is found near the surface of the oil in the tank.

Any settling tank should be of ample size to allow the oil to flow through at minimum velocity. Thus the oil entering at one end has an opportunity to drop out a considerable amount of its entrained moisture before it again reaches the pump suction at the other end. The tank should be kept as nearly full of oil as possible (due consideration being given to the expansion of the latter when heated for reconditioning purposes) because a full tank reduces the exposed surface on the inside of the tank and prevents excessive sweating. It also aids in the cooling of the oil and allows more time for the oil to drop out its moisture.

It is good practice to alternate the service of such tanks, thus allowing a batch of oil to be in service 1 week and then rest for a week. This is a safety factor against formation of emulsions.

Protecting the Oil in Service. Lubricating oils for circulating systems must be most carefully protected to assure continued lubricating ability. Sludge is an ever-present possibility if bad water conditions prevail. This is why bearing and machine manufacturers include such effective methods of sealing against entry of water and solid foreign matter, which also is a deterrent to good lubrication.

---

* For details of construction see manufacturers' catalogues.

Regardless of these precautions, however, water will often gain entry. The only recourse, therefore, is to remove it before it can lead to the formation of emulsions and certain types of sludge. Here the reconditioning system and oil filter play a most important part. In a relatively water-free system, however, sludge can be present in the absence of an emulsion, especially in an oil readily susceptible to oxidation. Furthermore, sludges can be either water-soluble or oil-soluble.

Emulsions are largely prevented by continuous removal of water. Along with sludges they can be eliminated by centrifugal purification. Filtration, in turn, will remove solid contaminants and oxidizable material. In any filtering element the uniformity of the filtering mediums must be maintained. Variation in pressure drop across the filter mediums due to plugging is not desirable.

Water traps and settling tanks in the circulating system have been found to aid materially in removing a considerable amount of water before it has time to affect the oil. All points where water may gain entry into such a lubricating system should be carefully sealed as added insurance. This can be accomplished sometimes by caulking surface joints with oakum and covering with molten lead.

With bearings, however, attention should be directed to their original design in order to provide for some recognized method of sealing which will not impair the free rotation of the shafts. The roller-bearing designer has achieved outstanding success in working with industry. Some of the newer machines are so completely equipped with sealed roller bearings and oil filtration that the color of the oil in circulation is scarcely changed after months of operation.

Methods of Sealing. Modern sealing methods have also been carefully studied to determine their adaptability to the oil-lubricated sleeve-type bearing. The perfected design of this bearing will rarely permit the entry of an excess of actually solid foreign matter. Water leakage, however, may occur, or there may be some accumulation due to condensation. Seal investigation has, therefore, been directed towards reducing this water content. Brass rings, the expanded leather cup, and the compression type of rubber seal have all proved their adaptability and are widely used today for the protection of such bearings.

BALL- AND ROLLER-BEARING LUBRICATION

Ball and roller bearings, commonly called antifriction bearings, are used on motors, line shafting, and other industrial machinery where protected lubrication is necessary. They can be oiled, prepacked with grease, or provided with fittings for pressure grease lubrication.

Particular makes of ball bearings will differ according to the design of the housing and type of lubricant seal used.

In the roller bearing the design of the rollers will be an added characteristic. Rollers generally are either solid or flexible. The latter are always cylindrical in shape, the distance between the inner and outer raceways being the same over the entire length. Solid rollers, however, may be either cylindrical, tapered, or barrel-shaped.

In any case the rolling elements of antifriction bearings will be carried or housed in much the same manner, *i.e.*, in suitable containers comprising raceways and cages. Between these latter are located the balls or rollers. They are kept in their proper position with respect to the races and to each other by the separator, cage, or retainer. In a typical design the inner race will fit on the shaft or journal, the outer being held by the frame or other rigid part of the bearing housing. Rotation of the shaft sets up rotary motion between the rolling elements and the inner and outer surfaces of the raceways.

Ball and roller bearings involve rolling contact. Rolling contact is assured when the balls or rollers are held as nearly as possible in perfect alignment with the shaft. Then deflections under load are reduced. Some designers feel that it is impossible to eliminate entirely such deflections; they believe some sliding motion will always occur. Much of the friction developed is between the rolling members and the retainer or cage.

This is not serious since other conditions of operation may vary widely, as, for example, the speed of operation, the load, or the temperature. Any one of these in its normal variation between minimum and maximum production periods or summer and winter ranges may have considerable effect upon the performance of a lubricant within such a bearing.

For example, the operating speeds must be carefully considered. They influence the choice of oil or grease. The higher the speed, the lower should be the viscosity or body of the oil; 80 to 100 sec Saybolt Universal at the operating temperature of the bearing is the usual minimum limit.

The reason for this is that, as speed of operation is increased, the more rapidly will the lubricant in such a bearing be churned about, especially if the bearing has been overfilled.

Churning causes increase in internal or fluid friction within the lubricant and leads to increase in temperature. This is why oils of low to medium viscosity are preferred for the lubrication of high-speed antifriction bearings or as a component of greases designed for similar service.

Rolling motion in a ball or roller bearing must be maintained as perfectly as possible. If any one of the balls or rollers stops rolling, it will slide. This will be bad for their contact surfaces as well as for the raceways. This can be prevented by designing the bearing seal so that it will work with the lubricant to keep out abrasive dust, lint, water, steam, or acids.

Function of Lubrication. The general purposes of lubrication in such a bearing are

1. To prevent rusting
2. To facilitate as easy rolling as possible
3. To reduce friction where balls or rollers contact the cages or retainers
4. To serve as a seal to prevent entry of foreign matter

Easy rolling is attained by lubricating the balls or rollers and the retainer. To accomplish this, however, all the surfaces (which are of a highly polished nature) must be in as perfect condition as practicable.

Generally, as light a lubricant should be used as can be successfully retained in such a bearing, considering the operating temperatures, speeds, and pressures.

Types of Lubricants. When and where to use oil or grease for the lubrication of a ball or roller bearing will depend upon

1. The operating temperature range
2. The method of sealing
3. The range of operating speeds
4. The load conditions
5. The means provided for relubrication
6. The service conditions
7. The bearing dimensions
8. The possibility of contamination with liquids, solids, or vapors

These conditions naturally will vary widely, and their combination may be quite diverse. Some specific one, however, will usually stand out and suggest the type of lubricant that will give best protection of the bearing.

Oil Lubrication. Petroleum lubricating oils suitable for ball or roller bearings will vary over a wide range of viscosity—from virtual water fluidity to products as thick as syrup at room temperatures. One universal requirement always prevails: they must resist oxidation. Provided a petroleum oil meets this requirement, it can be relied upon to function dependably for long periods of hard service when kept free from contamination.

The choice of the most suitable viscosity will depend upon the bearing seals, the prevailing speed conditions, and the maximum operating temperatures. Generally, high speeds and average plant temperatures will require very fluid oils to reduce the internal or fluid friction as much as possible. In high-temperature service where speeds normally are lower, the oil viscosity must be increased. Specially refined cylinder oils are often used in such service.

Desirable Properties of Grease. Grease for ball and roller bearings should be as free as possible from acid-forming tendencies in order to ensure best protection of the highly polished metallic surfaces. The presence of any material that might lead to oxidation and corrosive reaction or to decomposition or settling is also objectionable.

A properly designed ball or roller bearing will require relubrication only about every 3 or 4 months. Often this period can be extended if the housing holds sufficient lubricant and an effective seal is maintained. *But never pack the bearing too full.*

What Is Grease? Lubricating greases are mixtures of petroleum oil and some kind of soap.

The petroleum oils used in grease making may vary from light pale oils of approximately 100 SSU viscosity at 100°F to heavy cylinder stocks. In some special cases even extreme-pressure characteristics may be required. The oils used should be of the proper viscosity for the service intended and should be well refined so as to resist oxidation and gumming.

The soap components should be just as carefully selected as the petroleum oil and should be made from nonoxidizing and noncorrosive fats which also are free from any foreign matter which might reduce the lubricating qualities. Antioxidation additives are today included to increase the stability of ball- or roller-bearing greases. The finished greases should not contain any fillers or abrasives which would affect the highly polished metallic surfaces of the bearings.

Types of Greases. Greases are divided into different classes according to their base or type of soap. These include calcium, sodium, mixed-base, lithium, aluminum, potassium, and lead-soap greases. Calcium–sodium (known as mixed base) greases predominate in the lubrication of antifriction bearings for industrial machinery.

Calcium- or lime-soap greases are made with a variety of mineral oils. They should be used only for average temperatures, up to, say, a maximum of 150°F; above this temperature the water used in their make-up evaporates gradually, then the grease may decompose, causing the oil and soap to separate. Recently, however, heat-stable lime-soap greases have appeared on the market. Such products do not separate when used at temperatures up to their dropping points; consequently their usefulness is greatly extended. They do not require water for stabilization.

Sodium-soap greases are even more resistant to heat and so can be used under higher temperature conditions.

A mixed-base grease contains a combination of calcium and sodium soap; such greases usually have the good features of both except that they do not have the fibrous characteristics of most sodium-soap greases. They are more like butter and require but little power on starting and running.

When carefully selected materials are used, mixed-base greases resist deteriorations and can be used to pack bearings that are to be stored for a long time or in service where the lubricant is used for long periods without relubrication. These greases can be used at moderately high temperatures, up to, say, 200 to 225°F, for their stability is uniform over a wide temperature range. When a grease is to be used continually at temperatures above 200°F, a frequent cleaning and relubrication routine should be followed.

Ball-bearing Requirements. The amount of lubricant used is very important as it affects internal friction and power consumption. Leading manufacturers advise that where oil is employed *the housing should generally be filled to a level just sufficient to submerge half the surface of the lowest ball when the bearing is idle.*

The viscosity or body of the lubricant becomes a decided factor under high speeds owing to excessive churning and development of heat through internal friction. Under extremely high speeds wick-feed or sight-feed drip oil lubrication has satisfactorily reduced churning and heat development.

When grease is used, however, a somewhat greater amount is permissible, the housing being charged from one-quarter to one-half full. Use of greater quantity may lead to drag, temperature rise, and abnormal power consumption.

Grease, owing to its seal-forming properties, is useful for any type of service where there is danger of contamination with dirt and moisture. Grease also can be very much more effectively retained in a nonoiltight housing. Conversely, dirt or grit that finds its way into a grease-lubricated bearing does not settle out but usually becomes well mixed with the grease, forming an abrasive.

Roller-bearing Service. When a roller bearing is to be lubricated with oil, much the same conditions apply as stated in connection with ball bearings. Where pressures or temperatures may be high, better lubrication will often result if somewhat heavier oils are used.

Heavier oils for roller-bearing lubrication should be chosen with the utmost care after careful study of the bearing temperatures, for it is very possible to overestimate the conditions of operation; then excessive drag may develop.

Where such bearings may be exposed to consistently high temperatures, pressure circulation of a comparatively fluid oil has been found to promote lower actual bearing temperatures. Where the oil acts directly as a coolant, it may in turn be cooled before recirculation.

In the grease-lubricated bearing, but little cooling effect is developed by the grease itself. If, however, grease has been prepared to meet the operating conditions, it will promote a uniform range of bearing temperatures by its ability to reduce friction, especially if it does not develop abnormal internal friction within itself.

Protecting Lubrication. A well-designed ball or roller bearing usually contains a good seal to prevent leakage of lubricant. Grease, in itself, will form a good seal if it is heavy enough, but it is best to rely on mechanical seals, for heavy greases may cause high power consumption. For this reason greases which are easily worked and which can be used under a wide temperature range are best suited to motor bearings and other bearings.

It is also important to study sealing devices wherever the bearings must operate under high temperatures. As indicated, the effect of such temperatures is to reduce the viscosity or consistency of a lubricant. The extent to which this will ocur depends upon the original body of the product.

Seal Design. In the earlier developments of bearing seals, felt- and leather-washer and grease-groove seals were widely used. They were comparatively inexpensive and simple in design. These advantages cause them still to be used by many bearing manufacturers for certain types of service.

Since their development, however, other types of seals have come into usage including metallic rings, similar to piston rings, and metallic springs for the purpose of maintaining the adjustment of felt, leather, rawhide, and cork against the shafting. Composition rings have also proved of value as an oil seal or to protect a grease-lubricated bearing against entry of water.

The chief objective in the selection of a suitable seal is to obtain a design that will wear least in service; otherwise the purpose may be defeated. Washer-type felt or leather seals will have this tendency, although the rate of wear will depend upon the quality of the material. Where adjusting springs are used in connection with similar material automatically to keep the seal in close contact with the shaft, this will counteract wear; also it will help the seal to keep in the lubricant, although the pressure developed may sometimes promote shaft wear.

Protecting the Seal. Control of the lubricant in the bearing is most important. For each ounce of fresh grease applied, almost an equal amount of used grease disappears—usually past the bearing seals to accumulate or drip onto some nearby part of the machine.

If the bearing operates at higher temperatures, this may be very serious, especially when the greases used may thin down excessively. The result will be the same as when grease is applied to the bearing under sufficient pressure to force it past the seal.

Cleaning and Flushing. Many ball and roller bearings have a plug at the bottom for draining. When cleaning is necessary, the plug is unscrewed, the bearing flushed, the plug replaced, and the whole relubricated.

In an oil-lubricated bearing it is practicable to provide an arrangement of nipples and pipe fittings terminating in a sight gauge glass. In this way not only is cleaning made easier, but also the oil level in the bearing can be observed.

Maximum protection of any antifriction bearing is assured only when the lubricating system is *free from foreign matter.* In certain types of operation, this can be more easily maintained than in others. The extent to which dust or dirt may be present in the air or thrown onto the bearing will be a factor.

Bearings should be flushed and cleaned at periodic intervals, say about once or twice a year for the average plant motor. A light slushing oil should be used for this purpose. Gasoline or other solvents should not be used, for these would tend to dissolve the mineral-oil content of any grease used, leaving a residue of insoluble soap.

The frequency will depend upon the design of the bearing, the type of seal, the extent to which dust, dirt, or water may be present, and the nature of the lubricant. In some plants it may be necessary to flush certain ball bearings every 3 or 4 months.

Pressure Grease-gun Operation. The grease gun is one of the most valuable tools in plant maintenance. However, if the pressure gun is not carefully handled, too much grease can be forced into a bearing housing. Also, dirt can be forced in if the operator forgets to wipe each fitting before using the gun.

Overlubrication may cause overheating especially if the grease is too heavy. Such overheating is brought about by excessive internal friction within the lubricant itself.

With certain types of grease abnormal increase in temperature may make the grease so fluid or may change its make-up so that oil separates from the soap in the grease. This reduces the lubricating value of the grease and causes loss of oil by leakage if the bearing is not well sealed.

INDUSTRIAL GEAR LUBRICATION

The ideal gear lubricant must possess certain very definite properties such as

1. Sufficient adhesiveness to ensure that it will remain on the teeth and resist the action of centrifugal force
2. Such a viscosity as to form a suitable film regardless of tooth pressures or temperatures
3. No tendency to harden or become brittle and chip off in event of exposure to abnormally low temperatures
4. Sufficient "oiliness" or lubricating ability to reduce to a minimum the friction that occurs between the teeth
5. Sufficiently low cost to enable it to be purchased and applied at a reasonable expenditure in comparison with the value of the service rendered

Spur, Bevel, Helical Gears, Etc. In any gear installation the pressures usually encountered will be high; they may be especially severe on the bearing surfaces inasmuch as a relatively small area of contact is involved. The pressure developed by this contact is constantly shifting as the teeth are subjected to varying directions of load application. If rolling contact alone prevailed, the intensity of such a load momentarily on any part of a gear tooth could be disregarded. But sliding motion as well is practically always present; this explains the abnormal wear that occurs where gears are not properly lubricated or where the tooth surfaces are subjected to a continual abrasive action.

There are numerous gear lubricants on the market which have been designed to meet these requirements. They will vary from fluid mineral oils to intricate compounds, some of which may contain "fillers." Fillers serve but one purpose in a lubricant: to increase the viscosity and weight. They possess no appreciable lubricating value. Therefore fillers should not be used as they are deceiving and may lead an uninformed user to feel that his lubricant is suitable, when in reality, it is affording comparatively poor protection against wear. The necessary adhesive characteristics may also be inadequate. As a result, when used under high-speed conditions or wherever the gears may come into contact with water, acids, alkalies, or chemical fumes, the gear teeth may lose their protective film of lubricant owing either to its being thrown off by centrifugal force or being washed from the wearing surfaces.

Worm Gears. Except where the speeds are very low and the loading relatively light, worm gears are generally enclosed and bath lubricated. Open worm gears must be lubricated according to the speed and size. Normally they require a lubricant that will adhere to the teeth and yet be fairly fluid. Enclosed worm gears, particularly where a hardened-steel worm operates with a bronze gear, are usually lubricated with compounded steam-cylinder oils or noncorrosive lead-soap lubricants. These rather heavy-bodied oils are necessary in worm gearing to resist the squeezing-out pressure exerted by the sliding tooth contact and to provide the protective film between the teeth which is depended upon to minimize the friction of the sliding motion inherent in worm gearing. At the same time they cushion the impacts between the teeth resulting from gear inaccuracies or unevenness of the load being transmitted.

In the average bath-lubricated worm-gear installation, either the worm or the gear is permitted to dip into the lubricant according to the size and arrangement of the gearing, thus providing a sufficient amount of lubricant on the teeth to afford a protective film but not enough to cause "drag."

Extreme-pressure Lubricants in Industry. The advantage of the extreme-pressure (EP) type of oil for industrial gears has been definitely proved. Iron, steel, paper, and rubber are but some of the leading industries that have benefited. In brief, there is a definite field for the EP oil of the right viscosity, as indicated in Table 18-3.

Table 18-3

Service	*Viscosity range, SSU, at 210°F*
For high-speed high-pressure gears	50– 75
For smaller units of medium speed where gears and bearings must be lubricated with the same lubricant	70– 115
For large units of medium speed where gears and bearings must be lubricated with the same lubricant	130– 150
For gears of large pinion stands where a separate system, using lighter oil, is used for the bearings	230– 275
For heavy-duty mill pinions and reduction-gear sets	400–1,000

Conditions of Operation. Gears may be either encased or exposed according to the nature of their service and the extent to which they require guarding or protection against abrasive matter or dust. Exposed gears may often present lubrication difficulties. Normally they will require a lubricant that will adhere tenaciously to the teeth and resist the action of centrifugal force, speed, and temperature changes.

Where tooth pressures are not abnormal and the teeth are not subjected to heavy shocks, the lubricant viscosity should be chosen accordingly. If the lubricant is too heavy, it will defeat certain of the advantages of lubrication by imposing more drag on the gears and increasing their power consumption. As tooth pressures increase, however, the viscosity of the lubricant should be somewhat higher in order to ensure that the film on the teeth will be able to resist the squeezing action of their surfaces, especially when sliding motion takes place. This condition warrants a lubricant of increased film strength.

The presence of considerable dust in the air as a result of materials processed, as in the cement or rubber industry, may cause exposed gear lubricants to become veritable grinding compounds if they are too adhesive to be regularly displaced by fresh lubricant. Here it may be necessary to compromise and use a much lower viscosity oil than would otherwise be desirable.

The heavy pressures that are customary on certain types of steel-mill pinions, rubber-plant mixers, or cement-mill kilns may squeeze out ordinary lubricants, permitting actual tooth contact and thus calling for the use of a mild EP lubricant.

The frequency of relubrication of exposed gears depends entirely upon the service conditions. They must never run dry, neither should they be overlubricated so that a sloppy condition will prevail. Experience will dictate the proper viscosity just as it will the best method of application. A grade suited to clean operation may not maintain an efficient lubricating film under dirty conditions.

Where heavy bearing pressures prevail, these, in turn, may be transmitted to the gear teeth to some extent. Sometimes adjusting screws are employed to regulate the pressure to suit the work. Widely varying duty may, therefore, be demanded of some reduction and driving gears. Where slower speeds are customary, the possibility of overheating or throwing of the lubricant is reduced, yet wear may be appreciable if a proper film does not coat the teeth completely.

Sliding motion is most likely to occur when the teeth first come into contact and as they become disengaged, the points of the respective elements developing a scraping action on the sides of the adjacent teeth. Both wiping action and squeezing may occur at these times. Wiping or scraping off of the lubricant is most apt to occur where the teeth are sliding; squeezing out is possible as maximum pressures are encountered. Wear will occur more rapidly at the points of approach and recess of the teeth owing to the sliding friction involved, whereas the intermediate tooth surfaces adjacent to the pitch line, being subjected to rolling action, will resist wear more effectively.

Methods of Gear Lubrication. Gear lubricants must be applied according to the design of the installation. We are most generally familiar with automotive practice where the gears in the transmission and differential are bath lubricated. Contrast this with industrial production, *e.g.*, the gears that drive the rolls on certain rubber machines which may be either bath or hand lubricated; the gearing on excavating machinery which is largely hand oiled; and turbine reduction gears which are lubricated by force feed. This latter method of lubrication is also now widely applied to enclosed-type steel-mill reduction-gear sets.

So a wide variety of conditions exists, each of which may require special consideration according to the design of the machine, the size and number of the gears, and the products being handled. Certain of the latter will be of a perishable nature such as foodstuffs, paper, and textiles. Gearing on the attendant machinery must be so lubricated that there will be practically no chance of the gear lubricant splashing, dripping, or being thrown onto these products.

Analysis of industrial machinery presents five distinct conditions pertinent to gear lubrication:

1. Where the gears are enclosed in a suitable casing, out of contact with the bearing lubricant, running either in a bath of oil or being lubricated by force feed
2. Where gears run in an enclosed case, the gear lubricant at the same time serving the bearings, as is true in the majority of industrial gear drives
3. Where gears are entirely exposed, the lubricant being applied by hand
4. Where the gears run exposed but with their lower portions encased so that bath lubrication is possible.
5. Where gears are open and exposed to such dirty conditions as to render practically any lubrication ineffectual

Where and when to use any specific grade of lubricant is, therefore, often quite a problem. It is disconcerting to attempt to heed all the modern arguments in favor of industrial-plant efficiency and at the same time have a set of gears that may refuse to function properly with ordinary methods of lubrication. Such conditions are not entirely hopeless even though perhaps the air may be filled with dust or the gears subjected to hot water or acids, etc. The petroleum industry has solved this problem by developing specialty lubricants refined so as to stick and lubricate even when totally submerged in practically boiling water.

There are available similar lubricants for pressure conditions as already mentioned. These along with the wide range of straight mineral gear lubricants will serve virtually any condition of operation or means of application. It requires only judicious study of these conditions along with the physical characteristics of the lubricants and the application of the gearing.

Clean Conditions Promote Good Lubrication. Where pans are furnished for bath lubrication, they should be cleaned out at regular intervals since any dust that may have gained entry may destroy the adhesiveness of the gear lubricant, tending to form a pasty mass which the gears cannot pick up.

Where the gears dip in a bath of lubricant, this bath should be only so deep that the lowest teeth are just covered. This will give ample lubrication and keep the consumption at a minimum.

When the lubricant is applied by hand, it should be heated, if necessary, to reduce it to the consistency desired and painted on with a brush or poured on from a dipper as the gears are slowly revolved towards each other. Applying it in a fine stream or by spraying is most economical and effective.

Gear lubricants should be applied to open gearing relatively frequently and in small quantities rather than in considerable volume and at longer intervals. Thus there will be less wastage and less danger of gobs of lubricant being thrown off by centrifugal force to contaminate the products passing through the machine. In case the lubricant becomes laden with foreign material and packs at the roots of the teeth or between the gear and its shield, this cake often can be softened and removed by the use of kerosene or some petroleum solvent. When there is trouble, see Table 18-4.

Cautions—Gear Lubrication. Check alignment of driving- and driven-shaft connections.

Inspect after first half hour after starting. Evidence of improper selection of lubricant often shows up during this period, or evidence of misalignment may be indicated.

Table 18-4

Condition	Most prevalent on	Cause	To correct it
Abrasive wear or scoring	Spur, helical, bevel gears	Misalignment or rough surfaces; improper tooth contact; sliding under heavy load; too low oil viscosity; low starting temperatures	Increase oil viscosity; use oil with mild noncorrosive EP additive; use means for preheating to raise the starting temperature
Galling	Spiral-bevel, hypoid gears	Oil-film rupture, high surface temperatures	Use oil with mild noncorrosive EP additive; use means for cooling to reduce temperatures
Pitting	Any or all types of gears	Occurs with rolling as well as with combined rolling and sliding with oil too low in viscosity. More prevalent on rough-surface finishes or where local tooth overload prevails	Use an EP oil; increase the oil viscosity; try to get gears of better surface finish; increase the surface hardness or metal toughness. Improve tooth alignment and load uniformity by shimming under bearings or adding outboard bearings to overhung pinions
Burning	Any or all types of gears	Overload or lack of lubrication	Run under conditions for which gear was designed. Lubricate

Watch the oil level. The amount of oil in an enclosed gear unit is often just as critical as the kind of oil.

Check oil level when machine is standing still; if checked while running, a false level may be indicated.

STEAM-CYLINDER LUBRICATION

Steam-cylinder oils must be of comparatively heavy body and possessed of high "wettability" in order to ensure that the lubricating film will cling to the valve seat and cylinder walls, withstand washing off by the steam, and resist the wearing or scraping effects of valves and pistons.

Viscosity or body is attainable by suitable refining.

"Wettability" is obtained by judicious treatment of the cylinder stock and the addition of certain fatty oils to obtain an emulsifying effect.

An oil having a viscosity range of between approximately 100 and 220 SSU at 210°F is generally required according to

1. The steam pressure and temperature involved
2. The type of steam valves
3. The means of application available

Cylinder oil may be classified according to viscosity as follows:

1. Light-bodied—100 to 120 SSU at 210°F
2. Medium-bodied—120 to 150 SSU at 210°F
3. Heavy-bodied—150 SSU (or above) at 210°F

Lubricant Distribution by Steam. The best way to get cylinder oil to all desired points is to use the steam itself as a carrier. The steam reaches all moving elements inside the valve chambers and cylinders with the possible exception of parts of certain types of Corliss valves.

If the oil is divided into minute globules and intimately mixed with the steam, only a very small quantity is required. The extent to which the oil is atomized will control both the efficiency of lubrication and the quantity necessary.

The more complete the atomization and the more thoroughly the oil is dispersed through the steam, the better will be the lubrication of the engine and the more economical the consumption of oil. Atomization is influenced by

1. The condition of the steam
2. The point of introduction of the oil
3. The velocity of the steam
4. The character of the oil

Factors Affecting Atomization. High steam pressure and temperature will atomize a given oil faster than low steam pressure since high temperatures thin down the oil to a greater extent. So a comparatively heavy-bodied oil may be atomized by a high-pressure steam as quickly as a light-bodied oil will be atomized by a low-pressure steam.

Conversely, low-pressure steam requires a lighter bodied oil in order to obtain efficient atomization. The point of introduction of the oil into the steam is also a factor; the farther this point is from the cylinder, the greater will be the opportunity for complete atomization.

Locating the Point of Introduction. If the oil is introduced directly into the valve chest or just above the throttle, a product must be used that will distribute itself very rapidly through the steam. Conversely, if the point of introduction can be located from 4 to 6 ft from the cylinder, the oil does not have to be able to atomize so readily as there is more time for the steam to develop the necessary atomizing effect.

If a heavy-bodied oil is used to meet the cylinder conditions, better lubrication may be secured more economically by locating the atomizer farther back from the cylinder.

There is a limit, however. If the oil is injected into the steam too far from the cylinder, too much condensation of oil on the sides of the steampipe will occur. This will increase the oil consumption, as the oil will run down into the steam chest without atomizing. Ultimately, it may cause detrimental gummy or carbonaceous accumulations.

How to Judge Effective Cylinder Lubrication. The condition of the cylinder, valve seat, and valve surfaces indicates the effect of lubrication. If valves function without undue noise and if there is a light film of oil on the piston rod, the engine should be well lubricated. Some oil in the condensate is also a good indication.

Time is necessary for the lubricating film to form and function properly; a hasty decision as to the suitability of such an oil should never be made. Any test should cover a period of several weeks. Then the engine should be shut down and the cylinder head and valve-chest cover removed to enable inspection of the interior. If there seems to be a film of lubricant sufficient to penetrate and leave the time-honored brownish stain on three or four thicknesses of cigarette paper, the surfaces may be regarded as being properly lubricated. Further evidence is a high polish and a color varying from bright iron white to steel blue.

Indications of Imperfect Lubrication. Rough, dry, dull, or rusty surfaces indicate that lubrication has either been insufficient or the wrong grade of oil has been used. In addition, if the stain on the cigarette papers appears streaked, blackish, or mottled, either the oil has been subject to carbonization or abnormal wear has taken place.

Lack of lubrication will also sometimes be indicated by sticky valves or groaning sounds from the cylinder when the engine is running. With Corliss-valve systems, slowness in action of the dashpots indicates insufficient lubrication.

Exhaust Steam Is a Guide. If the condensed steam shows considerable quantities of liquid oil, either too much oil is being fed, or it is not properly atomized.

If it shows minute drops of oil and is milky in color, it is probable that atomization is complete and the feed is correct.

If there is a film of oil on the piston rod and no oil has been fed directly thereto, it can be taken as an indication that atomization is satisfactory and that the surfaces are receiving sufficient oil.

Pools of oil lying in the bottom of the cylinder or in the counterbore indicate excessive lubrication. This can be determined, however, only at the time of engine overhaul.

A suitable film on the piston rod, minute drops of oil, and a milky appearance in the condensate, free action, and little or no noise in valve operation are indications that the oil is suitable, atomization complete, and the rate of feeding is about right.

Selecting the Oil. Pressure, temperature, and moisture must all be considered in selecting the oil, for each will have a decided influence upon effective lubrication. There is more or less of a relation between these conditions, also the steam velocity and the use which is to be made of the exhaust.

Temperature Depends on Pressure and Superheat. The operating temperatures in the steam cylinder and valve chest are most important. It can be noted from standard steam tables that temperature is directly related to the pressure:

1. As oil viscosity varies inversely with temperature, it will be decreased as steam temperatures are increased.
2. Where operating with high-temperature saturated or superheated steam, a heavier bodied oil should be used.
3. Conversely, where steam pressures are low or where a partial vacuum with accompanying low temperatures exists, a lower viscosity, more easily atomized oil is necessary.

The heat of the steam does not noticeably affect the rate at which a well-refined cylinder oil will be oxidized. For example, consider "the operating temperature" for saturated steam at, say, 600 lb, which is 486.6°F. This is below the open-cup flash point of any cylinder oil. Furthermore, it is possible that the flash point would be raised with increased pressure. As a result, there does not seem to be any reason to believe that a very high flash or fire test is necessary.

Saturated steam always contains moisture, and as there is relatively little oxygen present in the steam, it does not seem likely that ignition could be produced in the cylinder regardless of the flash point of the oil. There are some, however, who advocate using means for deoxidizing the steam and make-up feed water to retard corrosion of boiler tubes and steam lines.

Velocity Improves Atomization. Atomization of a cylinder oil is improved as the velocity and temperature are increased. The higher the temperature and velocity, the more readily will a heavy-bodied oil be atomized owing to the reduction in viscosity which occurs at the temperature of atomization. These conditions must be taken into account when deciding on the initial viscosity of the oil.

Moisture Requires Compounding. To secure proper lubrication under wet-steam conditions, it is necessary either to increase the rate of flow of a straight mineral oil or substitute an oil that contains a certain percentage of fatty compound such as lard oil, degras, or tallow.

Steam will always contain a certain percentage of moisture unless it is superheated to a sufficient extent to counteract any line and cylinder condensation which may be caused by the cooling effect of the piping or cylinder walls and the expenditure of heat by the expansion stroke.

Compounding develops an emulsion through reaction of the compound with the moisture in the steam. The lubricating film thus has a greater affinity for the cylinder walls and other wearing surfaces and becomes more resistant to the washing action of the water in the steam. The greater the percentage of moisture in the steam, the higher should be the fatty compound content of the lubricant, although 10 to 12 per cent is the usual maximum.

An excessive amount of fatty compound beyond that necessary to form the requisite emulsion will not improve the lubricating value of the oil. It may even be objectionable, as exposure to high temperatures can cause some fatty oils to decompose and form carbon and corrosive acids.

It is best to use just enough compound to conform to the moisture conditions of the steam and maintain a suitable film of oil on the cylinder walls. It is best, therefore, to reduce the quantity of compound and improve the quality.

Where Compounding Is a Detriment. The property that causes compounded oils to unite with water to form emulsions in the cylinders also prevents ready separation from water in condensed steam; likewise, the more completely the oil is atomized, the more difficulty it will have in separating from water. Obviously this will cause trouble where the condensate is used for make-up or led to open feed-water heaters.

Oil emulsions in a boiler combine with the boiler compounds to cause foaming or with the boiler impurities to produce a coating over the tubes and fire surfaces. This coating seems to form more readily over clean tubes than over dirty ones. A very thin layer of oily sludge over a tube or shell surface will so insulate it that there is not only a large loss in heat efficiency, but the rise in temperature of the metal may be so excessive as to cause burning out or explosion of the boiler.

Table 18-5. Quantity of Steam-cylinder Lubricant Required per 10-hr Day

Drops per min	Cylinder size, in.	No. of pints in 10 hr
4	8 × 8	0.4
8	12 × 12	0 75
16	18 × 18	1 5
24	24 × 24	2.25
32	30 × 30	3.0
40	36 × 36	3.75
48	42 × 42	4.5

Even if exhaust steam is used only for heating, the heaters may become coated with oil and lose in efficiency. This is also true if exhaust steam is used in tube and shell feed-water heaters. Likewise, in condensing engines an unsuitable oil will form layers on the condenser tubes with consequent loss of vacuum and thermal efficiency.

Where Straight Mineral Oils Should Be Used. Where the presence of a fatty oil in the exhaust steam is objectionable, it may then be advisable to use a straight mineral type of cylinder oil. However, as an increased amount is necessary to ensure proper lubrication, imperfect atomization may result. In consequence, oil accumulations in the cylinder will be prevalent and carbon deposits developed.

This will be especially true in multiple expansion engines equipped with receivers and reheaters, the high temperatures to which the oil is subject being very conducive to carbonization. In poppet-valve engines carbon formation of this nature may often cause imperfect operation of the valves. In any case, some carbon accumulations may form around the rings.

Table 18-6. External Lubrication for Reciprocating Engines

Lubrication system	Speed	Rod diam	Grade of oil	Viscosity of oil at 100°F, SSU
Hand-oiled or drip-feed oil cups.	High	1½ in.	Red engine	100–200
	Medium	1½–3½ in.		200–300
	Low	Over 3½ in.		300–500
Ring or chain oilors.	All	All	Pale	180–300
Splash lubrication.	All	All	Pale filtered	150–300
Circulating systems. . . .	Medium	Small and medium	Pale filtered	150–200
Circulating systems.	Low	Large	Pale filtered	200–300

Note: Reference to speeds in general for reciprocating engines is considered to be in the following range: low speed—below 50 rpm; medium speed—50 to 150 rpm; high speed—150 rpm and up.

AIR-COMPRESSOR LUBRICATION

In compressing air, heat is developed, caused by the rapid increase in the rate of impact between the molecules of the air involved. Actual friction contributes but little to the total amount of heat developed. Normally most of the machine friction will be dissipated by radiation or conduction.

The air compressor, however, is not a heat engine, for the heat developed during compression is largely removed from the compressed air by cooling.

Obviously, the air compressor must be lubricated. Furthermore, this must be done at fairly high temperatures, for the heat of compression is not removed until after discharge. Thus, the piston, cylinder walls, or vanes, according to the type of unit, become heated.

Air-compressor Cylinder Oils. These oils must be capable of withstanding heat with minimum tendency towards oxidation. All lubricating oils will be subject to more or less partial distillation under high temperatures. As this continues the lighter portions evaporate and are carried off with the discharged air, the heavier fractions meanwhile remaining in the cylinder or collecting in the heads or on the valves.

These oily deposits gradually thicken, carbonize, and collect any dust which may pass in with the air, finally developing to such an extent that they may interfere with the operation of the valves. Hence the advisability of using a suitable air filter.

It is usually the dust from the air along with gummy oil deposits (known as carbonaceous matter) from improperly refined oils or excessive use of oil which causes faulty valve action.

Cooling. Means of cooling and the availability of adequate ventilation or cooling water (depending on whether compressors are air- or water-cooled) are most important considerations with respect to lubrication, especially when dealing with portable compressors.

Most effective lubrication is attainable where the walls can be kept sufficiently cool to preclude vaporization of the oil film. Suitable fins around air-cooled cylinders and water-jacketing those which must be water-cooled take care of this.

Intercooling Protects Lubrication. Intercooling, where two or more stages are involved, assists in reducing the temperatures to which the oil is subjected. Along with aftercooling, it also aids in condensing oil vapors and any moisture that may have been taken up by the compressed air. This helps to increase the amount of air compressed per horsepower.

Therefore, wherever practicable, air should be suitably cooled to nearly the inlet temperature of the cooling water or the atmospheric temperature of the air in an air-cooled unit.

In this way oil is protected both in service, as a lubricant, and afterwards against blame as a possible cause of explosion. If the oil should be used to excess and not be entirely removed from the discharge air, the temperature of the latter, after suitable aftercooling, is normally too low to cause combustion or flashing of the oil.

Aftercooling Reduces Danger of Explosion. The aftercooler in turn is effective in correcting explosive conditions. It reduces the temperature of air discharged to the lines and removes excessive oil vapors which may have formed owing to improper lubrication.

Compressor-oil Characteristics. Air-compressor lubrication may present a problem due to the nature of the operating conditions to which the oil will be subjected. There may be a considerable temperature range; furthermore, as this may approach quite a high maximum, there may be considerable possibility of oil oxidation or combustion, with the accumulation of more or less carbon residue according to its base and refinement.

It is important to realize that enclosed mechanisms or interior surfaces are involved which do not enable easy inspection. They may be rotating or reciprocating, according to design, but all involve sliding friction.

Load conditions also may influence lubrication especially where high piston-ring pressure is involved. In addition, the operating conditions may be contradictory, for example, where a large loose-fitting piston might require a heavy oil but where the speed conditions would indicate that a lower viscosity oil might function best.

The function of lubrication is to prevent metal-to-metal contact. Theoretically, the variety of conditions which affects the performance of the oil might indicate that selection of the lubricant would be quite complicated. Actually, however, it simply involves the use of an oil of adequate stability and suitable body or viscosity.

Viscosity. Viscosity or body is related to piston ring or vane seal according to the type of machine; consequently, it affects the efficiency. If the oil is too light in body or too low in viscosity, it may not furnish the required seal at the peak temperatures of compression. This may result in increased oil consumption or air leakage.

It is related to the ultimate development of carbonaceous residues, for an increase in the rate of oil delivery is often the first thought. This only adds to the volume of oil that may be subject to deposit formation.

In turn, if the oil is too heavy or of too high a viscosity, it may be sluggish at intake temperatures, subject to imperfect atomization, apt to have too much internal friction, and likely to hold nonlubricating foreign matter more tenaciously than a lighter oil. It will also not be so readily subject to partial distillation, but the amount of carbon deposit developed will be proportionately higher.

The usual viscosity range for reciprocating-compressor service will be from 200 to 500 SSU at 100°F. For rotary (blade- or vane-type) units, somewhat heavier oils are preferred to maintain the seals, *i.e.*, from 50 to 125 SSU at 210°F, according to the design and operating conditions.

The rotary type of machine will normally require a heavier oil than the reciprocating unit (for the same compression range) owing to the scraping action of the blades against the cylinder wall as they are impelled outward by centrifugal force as the rotor turns.

The oil must not only maintain a suitable film on the cylinder walls to provide a running surface for the blades but it must also lubricate the slots that hold the blades.

Flash Point. The fact that oil vaporization may occur in air-compressor cylinders requires consideration of the flash point or that test which is indicative of the relative initial volatility of the oil.

There should be no flame or spark in an air compressor, so the flash point is not a measure of explosion possibilities.

Oils that show the highest flash points will usually develop the most carbon residue. Furthermore, this may be hard, adhesive, and resistant to removal either with the discharged air or by mechanical means.

To connect the flash point with the possibility of compressor or air-line explosion is unwarranted unless there is some adverse condition of construction or operation. For example, the use of dirty air along with an unsuitable (gum-forming) lubricating oil may have built up restrictions at fittings or bends in the air lines.

Whenever such obstructions have become extreme and become incandescent by increase in air friction, if the oil content in the air is high, failure of materials may occur owing to reduced tensile strength through overheating, irrespective of the vaporization tendencies of the oil. Otherwise, the oil would have to be subjected to a temperature far in excess of the laboratory flash point or even its spontaneous-ignition temperature before actual combustion could occur.

The safest procedure is

1. To use sparingly a suitable compressor oil of the lowest possible carbon-forming tendency
2. To see that the air is cool and clean
3. To check the discharge valves for leakage periodically
4. To be sure the oil has a high spontaneous-ignition temperature

Carbon. Carbon is caused by exposing an oil to direct heat and air. This involves a chemical change. If this heat is sufficiently intense, it causes abnormal vaporization of the more volatile constituents to result in accumulation of nonlubricating (oxidized) matter which may be of tarry or gummy nature. Continued exposure of the latter to heat causes coking or baking in piston-ring grooves, on valves, or elsewhere in the compressor.

The cleaner an oil will vaporize, the lower will be the amount of objectionable residues. Normally carbon residue will vary directly with the viscosity as well as with the flash point. A distillate compressor oil such as is customarily used for normal conditions (within the viscosity ranges mentioned above) should show a carbon-residue content well below 0.50 per cent by the Conradson test.

Any such residual matter would be of a gummy nature and would tend to hold any dirt or dust taken in with the air. Therefore, the latter should also be as clean as possible; a suitable air filter will assure this.

Application of Compressor Oils. How compressor oils are applied is of considerable importance in the ultimate development of effective lubrication. It is as vital as selecting oils of the proper physical characteristics, for if the rate of oil delivery cannot be properly controlled, the possibility of future difficulties due to carbon formation will be increased.

Point of Delivery. Air-compressor oil will function best when completely distributed over the cylinder walls.

On larger units the oil is usually pumped into the cylinders themselves by a mechanical force-feed oiler. On smaller units, splash may be used. Where controlled lubrication is possible, on account of the small amount of oil involved and the fact that a filtered oil is more readily atomized, the lubricator is generally located fairly near the intake or cylinders as atomization is effected in a relatively short distance.

In this manner the possibility of overfeeding oil to any particular part is reduced; oil flow stops and starts with the compressor, and the requisite lubricating and sealing film is more nearly assured.

Force-feed lubricators are not affected by variations in air pressure, and they will feed the oil at the desired rate in accordance with their adjustment, the speed of the compressor, and the viscosity of the oil.

Oil Control. It is inadvisable to establish any hard and fast rule in regard to the theoretically proper amount of oil that should be supplied to an air-compressor cylinder. There are too many variables involved such as the size of the compressor, its speed, and the condition of the piston and cylinder walls.

The main point is to avoid overlubrication since more trouble will be caused by the use of too much rather than too little oil. Any excess of oil will probably remain in an air-compressor cylinder considerably longer than in the cylinders of either a steam or internal-combustion engine since there is less atomization (owing to lower temperatures) and little or no washing action or dilution of the oil film.

As a consequence, very much less oil will be required per unit of cylinder surface over the same time interval. In theory, about two drops a minute should suffice. As this may not provide sufficient oil at the uppermost parts of the pistons and cylinders in horizontal machines to ensure satisfactory lubrication, the oil feed is generally increased above the usual theoretical requirements. This must not be done to excess, however, since it may lead to the collection of oil pockets in low parts of the machine.

During inspection, if the discharge valves have an oily appearance, enough oil is being fed to the cylinders; on the other hand, if the parts appear too oily or little pools of oil are found in compressor pockets or in any of the air lines, oil is being fed in excess of that required, or it has been improperly distributed.

Another rule states that from one to two drops of oil per 500 to 1,500 sq ft of cylinder area covered by the piston per minute (in reciprocating machines) should assure adequate protection in average service.

The size of the drops of any oil will vary with the viscosity, the temperature, the service conditions, the diameter and shape of the lubricator orifice, and the type of design of the lubricator, *i.e.*, whether it is mechanical force feed or sight feed.

The number of drops per pint will vary. As a result the number of drops secured per minute from an oil having a viscosity of 200 SSU at 100°F would differ from the number obtained from an oil of 300 SSU viscosity.

It, therefore, is not considered good practice to make an absolute recommendation as to the number of drops per minute that should be used in air cylinders of various sizes on account of the great variation in operating conditions that will be met.

Two compressors of the same design and size and built by the same manufacturer may, in fact, be operating in a room under identical conditions, yet it will be practically impossible to secure the same fit of piston rings and valves and the same polished cylinder surfaces. Experience has shown that two such compressors may require a surprisingly different amount of oil for air-cylinder lubrication.

If an oil is unsuitable for compressor service, an excessive amount may be required to keep the pistons operating freely, but excessive oil will cause carbonization in the air passages, particularly on the discharge valves. Sticking of these valves, with the passage of hot compressed air back into the compressor cylinder, is generally indication of overlubrication.

REFRIGERATION-MACHINERY LUBRICATION

Refrigerator-compressor lubrication must be studied with regard to its relation to capacity and efficiency. There must be adequate lubrication but not a continued excess, for immediately this latter occurs, the possibility of oil slugging will develop. This holds true regardless of the type of lubricating system employed.

The service involved and the operating conditions are important factors. Lubrication of such machinery is unique in that the action and effects of the oil upon parts not requiring lubrication, as well as upon the actual wearing surfaces, must be considered.

Disregard of such factors as the method of lubrication, the temperature in the expansion or cooling coils, the mechanical condition of the unit, and the location, type, and efficiency of the oil separator may frequently lead to marked increase in maintenance costs and reduction in capacity.

Oil congealed in any part of a cooling system will tend to reduce refrigerating efficiency owing to its becoming so sluggish under the low temperatures involved as to form an interior lining in the expansion coils and materially affect the heat transfer.

An oil for refrigerating-machinery lubrication must, therefore, remain fluid at the lowest temperatures to which it may be subjected during operation. These temperatures will be encountered in the expansion or cooling side of the system.

Should congealment occur, oil deposits may accumulate on the inner surfaces of the refrigerating piping to form more or less of an insulating medium which will prevent proper abstraction of heat from the compartment or material which is to be cooled. If this is allowed to continue, the capacity of the system will be reduced, and ultimately it will be necessary to clean out these congealed oil deposits.

Consideration must also be given to water. The oil at all times must be practically free from water; otherwise this will freeze if carried over to the cooling coils, in which case it would probably remain in the system and result in a certain decrease in evaporative efficiency. Water may also lead to ice deposits on certain of the valves.

When Viscosity Must Be Considered. Viscosity is a factor where enclosed-crankcase high-speed machines are used in connection with evaporating systems which may allow liquid refrigerant to return to the compressor. Oils should be used that will stand agitation in the presence of the refrigerant and a certain amount of water if present.

The one oil often lubricates the entire machine. As a result it must be capable of serving both the cylinders and the bearings. It should not emulsify to any great extent, for this might result in stoppage of the lubricating system or impairment of refrigeration should oil work past the piston rings and over to the cooling side.

The condition of the valves, piston rings, and stuffing boxes must also be considered in deciding upon the viscosity of the oil.

Practically as important as its lubricating properties will be its sealing and compression-forming ability. If the cylinder walls and moving parts are in first-class condition, a straight mineral oil having a viscosity of from 150 to 200 SSU at 100°F should afford adequate lubrication.

In large machines or in those where the cylinder walls are scored or rings are worn, an oil of higher viscosity may be essential to maintain the requisite seal and degree of compression. Under such conditions an oil having a viscosity of approximately 300 SSU at 100°F should be satisfactory.

Methods of Lubrication. The type and capacity of the compressor control the method of lubrication. The centrifugal machine requires the least complex system since there are only the bearings of the rotor to be lubricated. Ring oilers or pressure circulation are used for oil distribution. Simultaneously, the oil performs an additional function in maintaining an automatic oil seal against loss of vacuum.

Reciprocating or rotary compressors present more parts to be lubricated. Circulation of oil is accomplished by splash or force feed. The system involved for the lubrication of cylinders, stuffing boxes, and enclosed bearings will have a decided influence upon the grade of oil that should be used.

Splash Oiling. Splash lubrication is particularly applicable to fractional-tonnage units and also to vertical machines.

With this type of lubrication there is but little possibility of starved lubrication provided the compressor parts are designed for thorough circulation of the oil after this is begun by the crank splash elements. All that is necessary is to maintain a suitable oil level to enable the splashers to dip to a sufficient extent at each throw of the crankshaft.

Continued operation will result in the crankcase being filled with a lubricating vapor above the main body of oil which will ensure adequate lubrication of main, wrist pin, and crank-pin bearings.

Careful attention is necessary, especially when recharging the case with oil, to see that the level is not raised too high. If it is, churning by the crank can cause such violent agitation in the main body of oil as to retard effective precipitation of any solid impurities that may have gained entry. There would also be possibility of loss of lubricant past the piston rings with subsequent entry of an excess of oil into the condensing and evaporating parts of the system.

Piston-ring Fit. When piston rings are not sufficiently tight, if the crankcase contains too much oil or agitation is too violent, the excess which naturally will reach the cylinder walls will tend to work past the rings as so frequently occurs in an automobile engine.

This is not only wasteful but also a detriment, for oil in the refrigerating lines will impose an added load on the oil separator. Furthermore, if by chance the oil is not of sufficiently low pour test, there will be possibility of its congealment within the system with reduction in the amount of refrigeration developed.

Even with rings in good condition, oil pumping may occur owing to faulty design of the evaporator or careless operation whereby liquid refrigerant enters the cylinders from the evaporator.

Use of excess oil in a splash-oiled system will also involve the possibility of difficulty when draining and cleaning, especially where sludging has occurred.

Continued churning of improperly refined oils will cause sludge formation. In part this is due to oxidation. It will be most probable where water is present or the oil is laden with foreign matter such as dirt, metallic particles, or carbon.

Periodic cleaning must therefore be done with study of the condition of the used oil, for this will very often indicate both the approximate suitability of the latter and the extent to which effective lubrication is attained.

Pressure Systems. Pressure lubrication is widely used on larger types of vertical or horizontal machines. It assures accurate control of the amount of oil delivered to cylinder walls and compressor bearings. It is also possible to filter or purify the oil where there is provision for circulation.

Pressure lubrication is designed to function either alone or in conjunction with the splash system. The objective is to obtain positive circulation of oil throughout the compressor and to eliminate foaming as far as possible. The extent to which foaming may be objectionable will depend upon the oil level and to the location of the suction valves. With compressors that take suction through the crankcase, if the foam level rises to a sufficient degree, foam may be carried over to the high side with the refrigerant seriously to retard heat transfer. Ultimately, if allowed to continue, cleaning of the system may be necessary at considerable expense. To eliminate this, some builders have arranged their design so that all refrigerant gases and vapor are excluded from the crankcase.

Mechanical Force-feed Oilers. External lubricators of the mechanical force-feed type are extensively used where cylinders only are to be pressure oiled. Excellent economy will be attained by regulating such lubricators so that just enough oil is delivered to maintain the requisite lubricating films with the least amount of excess.

It is frequently good practice to lubricate internal and external parts individually. The mechanical oiler should be used with perhaps three outlets for cylinder and stuffing-box service and an independent circulating system for the bearings.

Mechanical force-feed oilers are especially adapted to cylinder and rod lubrication because of an oil lantern or oil recess within the piston-rod stuffing box.

By properly constructing a stuffing box with a lead to come from the lubricator it is possible to operate the piston rod continually through a ring of oil. In this way effective rod lubrication and sealing are maintained.

In some designs the cylinders can be oiled by feeding an excess of oil to the stuffing-box lantern and providing an overflow pipe to carry this to the refrigerant suction line.

This is similar to the principles of steam-cylinder lubrication, the refrigerating gas being impregnated with vaporized lubricant prior to its passage through the compressor.

Hand-pump oilers can also be used for this purpose, but mechanical force-feed units are more positive and require less attention.

Vertical compressors of the enclosed-crankcase marine type are best suited for automatic controlled systems. They are usually of comparatively small capacity and require but little attention beyond periodic inspection.

Pump Design. A variety of pumping devices is used for positive handling of lubricating oil throughout the compressor mechanism. The objective is to maintain controlled lubrication especially where dealing with refrigerants that are miscible with mineral lubricating oils. This necessitates consideration of strainers and oil separators in conjunction with pump design.

All are more or less related to compressor efficiency and capacity, *i.e.*, a continued excess of oil will lead to slugging and reduction in efficiency, yet there must be a slight excess on starting to ensure positive lubrication of piston and cylinder walls, especially in the reciprocating machine. This can be accomplished by proper pump adjustment.

The Gear Pump. The gear pump, based upon automotive practice, has been proved to be as equally dependable in refrigerator-compressor service. The gear pump as designed for positive delivery of oil is a comparatively simple device consisting of a pair of gears mounted in a suitable housing. The normal location of such a pump is in the base of the crankcase of the compressor. Some designers prefer to place it at the lowest part of the case; others are of the opinion that it should be set just above a depression or catch basin in the case to provide means for trapping foreign matter and preventing it from being circulated through the lubricating system. However, there will be a negligible amount of foreign matter in a well-designed system using properly refined oil.

Cylinder Wear. In the vertical machine the side thrust is taken directly by the cylinder wall which tends to make the cylinder wear to oval shape. This thrust varies at different points of the stroke so that the wear on the cylinder wall is not even over the entire stroke.

Horizontal compressors have connecting rods considerably longer than vertical machines, and the component of thrust at right angles to the travel of the piston is much less. This thrust is taken up by the crosshead guides which are readily accessible for adjustment. The only wear in the cylinder, therefore, is caused by that part of the piston weight which is unbalanced by the pressure of the guide and long stuffing box.

The Oil Separator. Wherever an excess of oil finds its way to the evaporating or cooling side, certain detriments will be involved. This is normally prevented by use of an oil separator.

This unit serves to remove any particles of oil from the refrigerant while it is in gaseous form after it has left the compressor. The larger the oil particles, the more effective will be the separator.

The capacity of any separator should be ample so that the velocity of the gas passing through will not be too high. But should an excessive amount of oil be fed to the compressor, a heavy load will be imposed upon the oil separator.

Location and Installation. The separator should be placed between the discharge of the compressor and the point of entry of the gas into the condenser. In certain machines a drain valve can be installed below the condenser to enable removal of any oil that may have passed the separator.

Where the oil separator fails to function properly, the reason is that it is set too near the compressor, the rush of hot gas preventing proper condensation and collection of the oil.

Oil will always vaporize to some extent owing to the heat which exists. This oil vapor will naturally tend to pass into the system with the refrigerant, to condense, and remain in the colder parts unless it is effectively removed before it enters the condenser.

This can be avoided by locating the separator as close to the condenser and as far away from the compressor as possible. It should always be of sufficient size to allow ample reduction in the velocity of the gas in order to permit effective separation.

A smaller separator located some distance from the compressor may often prove more effective than a large separator located nearby.

Where the main oil separator must be located adjacent to the compressor, an oil of as low an atomizing tendency as possible should be used. This property will usually accompany high viscosity. The choice of a heavier oil would, therefore, be advisable. In general, a viscosity of from 200 to 300 SSU at 100°F is satisfactory.

The efficiency of an oil separator can be checked by comparing the amount of oil removed from it with the amount fed to the compressor. Any extensive difference would indicate that the oil is not being entirely removed or trapped.

Allowance should be made for oil leakage around the stuffing box. To just what extent this may occur will depend on the installation, the care given to lubrication, and the viscosity of the oil.

Sealing the Stuffing Box. Suitable stuffing-box seals and properly lubricated piston rods are very important. Ammonia has a certain corrosive action upon brass, copper, and bronze. Stuffing boxes for such service are therefore built of cast iron or steel, using metallic, asbestos, or rubber packing.

The "Oil Lantern." In some types of machines a hollow space or "oil lantern" is located between two separate sets of packing.

This space surrounds the rod and is filled with oil. It not only serves as a seal to prevent loss or leakage of ammonia but also serves as an effective means of piston-rod lubrication. Lubricant is usually fed to the "oil lantern" by means of a hand or automatic oil pump.

Where the piston rod is efficiently lubricated, its surface will have a smooth gloss and will show a light film of oil. There will be no indication of overheating, and a relatively perfect seal will be maintained with a minimum of leakage.

In some types of double-acting machines, the "oil lantern" serves also as an auxiliary means of introducing the lubricant to the compressor cylinder by allowing oil to work past the piston-rod packing.

There is an added advantage to this method in that certain grades of packing which might be reacted upon by ammonia gas will be protected by the lubricant. This "lantern" can also be connected to the suction so that the outer set of packing is under low pressure.

Significant Physical Characteristics of Refrigerator Oil. *Pour-point Test.* Refrigerator oils are manufactured to pour points[2] ranging from −15 to −45°F, varying with the viscosity and type of oil. With the trend toward temperatures approaching −100°F in deep-freeze work, metals assembly, and medicine, very low wax-separation point has also become a factor. The pour point is associated with the wax content and viscosity of the oil. Thus, as either of these increases, the pour point will tend to rise. With some oils the recorded pour point may be due to both wax content and the viscosity or to the viscosity alone; in the case of the latter, the term "viscosity pour" is used. Oils derived from naphthenic-base crudes will ordinarily show a "viscosity pour," as these, by their nature, contain very little if any wax.

"Wax" Floc. "Wax" floc is variously interpreted as the temperature at which a 10 per cent oil −90 per cent refrigerant mixture, when chilled, changes from clear to hazy, or the temperature at which the mixture develops a definite floc.

The manufacture of wax-free oils has become increasingly important with the adaptation of refrigeration machinery to temperatures considerably below the conventional 0 to −25°F usage range. When a compressor, its lubricating oil, the expansion valve, and other parts must function at temperatures around −80 to −100°F or lower, it is important to consider the presence of any material in the oil that would congeal to interrupt the refrigeration cycle.

The petroleum chemist has spent much time studying hydrocarbons that would tend to congeal and solidify in the oil when exposed to very low temperatures. There seems to be no direct relation between the usual physical tests of these hydrocarbons and the pour test. Two refrigeration-grade oils may have practically the same physical characteristics including pour point, yet one may show a "wax" floc from 20 to 30° lower than the other. Obviously it is desirable to remove objectionable waxlike hydrocarbons in the course of refining the oils. This is the objective in modern refinery practice. When more positive information is available as to their true identity, the economics of the refining procedure may well be affected.

R. J. Thompson and W. W. Rhodes, of Kinetic Chemicals, Inc., in discussing Freon 22, have suggested some pertinent thoughts. Should oil separation, wax separation, and accumulation of wax at the low temperatures required be experienced, they state:

1. Use an oil as low in viscosity as is practical for satisfactory compressor operation.
2. Use an oil which has been dewaxed or degummed at a sufficently low temperature so that any remaining wax will not be precipitated out of the oil at the lowest operating temperature when the oil is in solution with liquid Freon 22.
3. Install an oil separator between the compressor and the condenser and as close to the cylinder head as possible, so as to prevent the oil containing wax passing through the condenser, receiver, liquid line, expansion valve, and into the low-temperature evaporator.

Water. Water in a refrigerator oil can exert several bad effects:

1. It can throw off the accuracy of the floc test by creating a false cloud.
2. It can contribute to chemical reaction with some refrigerants.
3. It can become a potential cause of stoppage owing to formation of ice particles at the expansion or regulating valve.

Water can be removed from the oil before the latter is charged to the refrigerating unit by blotter pressing which assures complete removal of suspended moisture from a new oil. For extreme low-temperature service, where it may be desired to remove even dissolved moisture at the time of charging the system with oil, this can be done by vacuum dehydration at elevated temperatures assisted by dry air or nitrogen. Where a refinery-dehydrated oil has been purchased, the storage must be so planned that the oil will not be exposed to air containing moisture. Petroleum oils readily absorb moisture from the air. A refrigerator oil, therefore, must be most carefully handled.

The Chemical Effect of Water. In an SO_2 system, water will react with the refrigerant to form a corrosive acid which can attack certain metallic parts of the system.

Water is serious in a methyl chloride system as it may produce corrosion products owing to slow reaction of the methyl chloride with water to form hydrochloric acid.

Table 18-7. Refrigeration-lubrication Chart

Refrigerant	Chemical formula	Primary use	Type of compressor	Behavior in presence of mineral lubricating oils	Approx. viscosity, SSU 100 °F	130 °F	210 °F
Ammonia.......	NH_3	Ice manufacture	Reciprocating	Some types of impure ammonia may cause sludge	155	82	42
Carbon dioxide	CO_2	Cold storage, ice manufacture	Reciprocating	No change	155 315 500	82 138 204	42 47 53
Sulfur dioxide. . .	SO_2	Electric refrigeration	Reciprocating	May go into solution to cause sludge or gums	155	82	42
Methyl chloride .	CH_3Cl	Electric refrigeration	Reciprocating	Mixes to cause reduced viscosity and lower pour test	315	138	47
Carrene No. 1 . .	CH_2Cl_2	Air conditioning	Centrifugal	Same as above	315 155	138 82	47 42
Freon 12......	CCl_2F_2	Electric refrigeration, cold storage, air conditioning	Centrifugal, reciprocating, rotary	Same as above	315 500	138 204	47 53
Freon 114.......	$C_2Cl_2F_4$	Industrial and electric refrigeration	Rotary, centrifugal or reciprocating	Same as above	315	138	47
Freon 11 or Carrene No. 2........	CCl_3F	Air conditioning	Centrifugal	Same as above	315	138	47
Freon 21..........	$CHCl_2F$	Air conditioning	Rotary	Same as above	315	138	47
Freon 113.	$C_2Cl_3F_3$	Air conditioning	Centrifugal	Same as above	155	82	42
Freon 22... ...	$CHClF_2$	Ultralow-temperature service, air conditioning	Reciprocating	Same as above	315	138	47

Water also can promote "sludge" formation and copper "plating." It is regarded by authorities as the chief offender in regard to copper "plating."

In systems using any of the Freon refrigerants, water beyond the point of saturation may promote reaction to corrosion products. Over long periods of time these refrigerants may slowly react with water and develop acid products to a sufficient extent to present a corrosion problem.

Significance of the Dielectric Strength.[3] A high dielectric strength is today used as an indication that a refrigerator oil will not contain moisture to such an extent as to cause trouble. While the dielectric strength does not indicate moisture content in terms of percentage by weight, there is some correlation between the two, *i.e.*, an oil of some 30,000 volts dielectric strength may contain as much as 0.01 per cent moisture by weight; a 25,000-volt oil may contain as much as 0 03 per cent moisture by weight.[4] Separation of any of this dissolved water by a slight drop in temperature will immediately lower the dielectric strength to 10,000 volts or lower. These quantities in ultra-low-temperature refrigeration can be considered harmful.

Relation to Moisture Solubility. Solubility of water in the oil is regarded as significant. Water in solution becomes water in suspension as the temperature of the oil is reduced owing to temperature-solubility effect. Research has indicated that moisture present in an oil up to its saturation point has little if any effect on the dielectric strength. Presence of moisture above the saturation point, however, immediately causes considerable loss in dielectric strength. The temperature is a factor. If an oil is saturated with moisture at a higher temperature and the dielectric strength is run at a lower temperature, a low value will be obtained at the latter temperature in contrast with a much higher value which may be observed at the higher temperature. This indicates the need for dehydration below any moisture content indicated by the dielectric-strength test if the oils are to be used in ultra-low-temperature service.

SILICONES AS SPECIAL LUBRICANTS*

BY MAURICE C. HOMMEL

Dow Corning Corporation, Midland, Michigan

Editor's Note. There is increased activity in the development of synthetic lubricants and the improvement of mineral-oil lubricants through the use of various additives and inhibitors. Since the Second World War the synthetic field has been developing rapidly. The armed forces and industry require low pour point (−40 to −80°F), low viscosity, noncorrosive fluids for use in instruments such as gun sights, recorders, compasses, fuse mechanisms, fire controls, and depth bombs. Ordnance and aviation equipment requires chemically stable and low-pour-point lubricants having nonvolatile characteristics. Lubricants possessing these qualities are the long-chain esters commonly referred to as "diesters." These synthetics have been employed successfully as lubricants in the liquid state, blended with mineral oils, or dispersed in various metallic soaps to form low-temperature greases. The latter have been successfully employed in aircraft and ordnance fire-control equipment. Lithium-soap greases made from diesters have shown excellent oxidation stability, low torque, and good lubricating properties.

Through various processes such as polymerization, chlorination, hydrogenation, and alkylation, a large number of important synthetic lubricants have been developed. Their use in industry is growing, although in general, the high cost of these materials is influential in preventing rapid industrial adoption as long as mineral oils are available at attractive prices. The polyalkylene glycols are being produced commercially and have been used successfully in many applications including high-temperature service, lubricants for rubber, heat-transfer systems, as hydraulic fluids, and in cutting and drawing operations. They are available as water-soluble or water-insoluble products in a wide range of viscosities. Like many of the other synthetics, the polyalkylene glycols have low pour points and high viscosity indexes.

Because of the rapidly changing synthetic picture, no effort is being made to cover the multitude of products that are available for specific services. The following subsection on silicones describes the unusual characteristics of one particular family of synthetics.

INTRODUCTION

Silicone oils and greases are perhaps the newest and most interesting contribution of high-polymer chemistry to the field of lubrication. The fluid silicones and the greaselike compounds made from them extend the temperature range of effective lubrication for certain applications beyond that now covered by petroleum oils and greases. This is a result of the heat stability of the silicone polymers combined with other desirable properties such as oxidation resistance, low volatility, inertness, high flash point, and water insolubility.

A variety of silicone products is now commercially available for specialized lubrication uses. All of them have as their basic structure a chain of silicon atoms, joined to each other through an oxygen atom with one or more organic groups attached directly to each silicon atom.

The inherent stability of silicone products is due to their chemical structure. Their skeleton of silicon–oxygen–silicon atoms is highly resistant to oxidation and to thermal decomposition. A wide variety of organic groups can be attached to the silicon atoms to alter such physical properties as viscosity index, lubricity, and pour point. The size of the silicone molecules can also be varied to affect such properties as intrinsic viscosity, flash point, and volatility.

SILICONE FLUIDS

Silicone fluids are made in a wide variety of types and viscosities. In all their various forms these liquid silicones are crystal clear, stable to heat and oxidation, incompatible with water and most organic materials, and inert toward metals. They vary considerably in lubricity depending upon their molecular size and chemical structure. The fluid types now available and of most general interest to lubrication engineers are listed in Table 18-8. A detailed description of each type will be given to aid in selecting the proper silicone lubricant.

Table 18-8. Physical Properties of Representative Silicone Fluids Useful as Lubricants

Principal use	Fluid type	Viscosity grade		Viscosity-temperature coefficient	Pour point (ASTM)		Volatility after 48 hr		Flash point, min deg, F	Lb per gal at 25°C	Specific gravity, 25°C
		Centistokes at 25°C	SSU at 100°F	$1 - \dfrac{V \text{ at } 210°\text{F}}{V \text{ at } 100°\text{F}}$	Deg C	Deg F	At deg C	Per cent			
High-temperature lubrication.....	A	500	1,060	0.89	−12	10	250	< 15	600	9.25	1.11
Lubrication at both high and low temperatures...	B	100–150	300–400	0.75	−48	−54	250	< 15	600	8.90	1.08
Hydraulic fluid (special metals)	C	100	355	0.60	−55	−67	200	< 2	600	8.08	0.969
Antifoam additive	C	1,000	3,500	0.62	−50	−58	200	< 2	640	8.12	0.973

Type A Silicone Fluid. The Type A silicone fluid was developed for general lubrication at temperatures above the range of most organic lubricants. It remains liquid down to 10°F (−12°C) and useful up to 500°F (260°C). This silicone fluid is comparable in lubricity to petroleum oils of the same viscosity at normal temperatures under light to moderate loads. At elevated temperatures, it is generally superior because of its high flash point, relatively low volatility, and freedom from gumming.

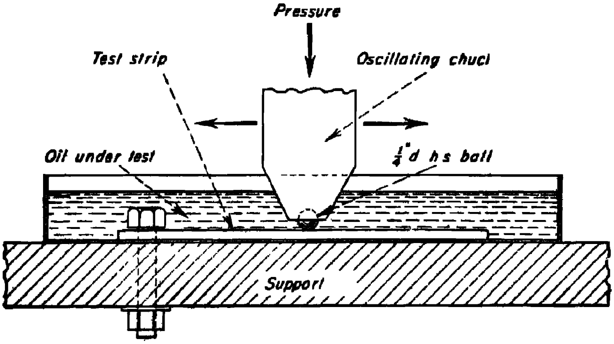

Fig. 18-5. Sliding-ball lubricant wear tester.

To evaluate the lubricity of this fluid at room temperature under various loads and between various metal combinations, a hardened-steel ball in a chuck was made to slide over metal strips covered with the test oil. Wear of the metal strip measured in terms of weight lost is plotted against time in Fig. 18-6 and against load in Fig. 18-7.

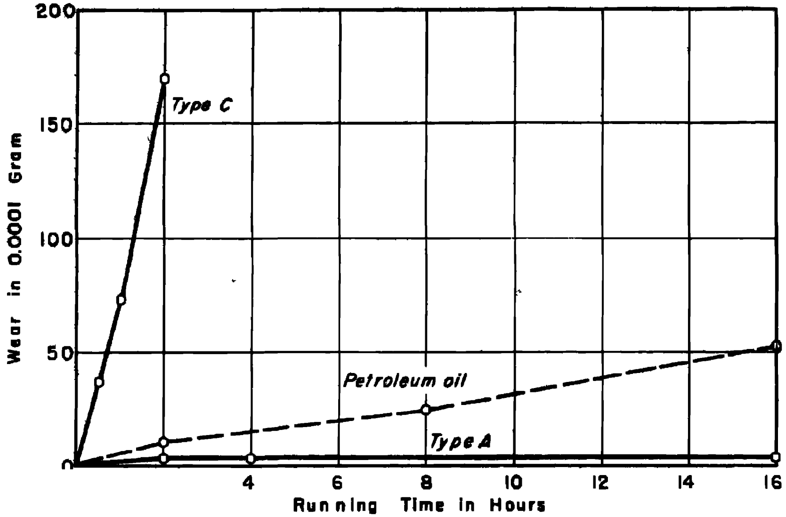

FIG. 18-6. Wear-tester results showing wear at various intervals of time when using a steel ball and a brass strip.

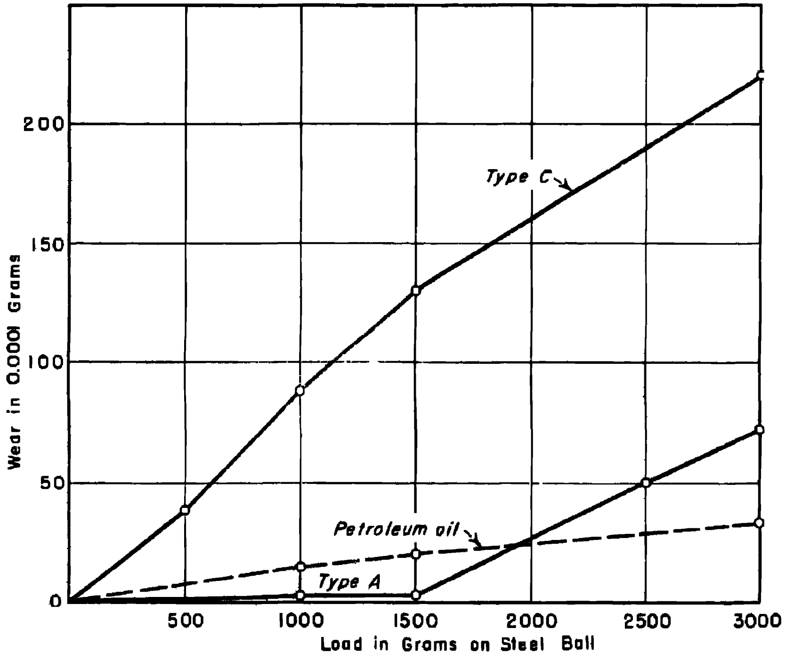

FIG. 18-7. Wear-tester results showing wear under various loads when using a steel ball and a brass strip.

Comparable values for an SAE 20 oil are also shown. The device used in this series of tests is shown in Figure 18-5.

Silicone oils of this type are used for lubricating mechanical devices such as clocks, instruments, conveyor bearings, and oven machinery exposed to high temperatures. Where high humidities are also involved, this silicone oil is available with a rust inhibitor added. An indication of serviceability as a lubricant for conveyor chains is given by a simple test device in which bicycle chains are cycled slowly through an oven at 350°F for 80 min, then through room temperature for 40 min, then through a humidity chamber for 80 min, and then back through room temperature to the oven. Conveyor chains lubricated once with this type of silicone oil remain operable for more than 500 days of such cycling, while an organic oil designed as a lubricant for oven conveyors oxidized and allowed the roller bearings to rust and freeze in 35 days.

Type A silicone fluid is normally supplied in a viscosity grade of 500 centistokes at room temperature, but higher viscosities can be made if the use requires them. It has the steepest viscosity–temperature slope of the silicone fluid listed in Table 18-8, but it has the same order of heat stability and oxidation resistance.

Colloidal graphite suspended in this type of silicone fluid is used for very-high-temperature lubrication because the silicone fluid completely wets bearing surfaces and carries with it the finely divided graphite to form a smooth and tightly bonded finish which has very good lubricity and permanence.

Type B Silicone Fluid. Type B silicone fluid is designed for use as a lubricating oil at temperatures ranging from −54°F (−48°C) to over 300°F (149°C). Its stability to heat is demonstrated by the fact that it does not gel or decompose to form gums after 1,000 hr of exposure to 482°F (250°C). Type B silicone oil has good lubricity under medium to light loads between hardened-steel surfaces and bronze, babbitt metal, or hardened steel, but it is not suitable for moderate to heavy loads or for bearing surfaces of cast iron or soft steel. This silicone fluid is also inert to metals but will prevent atmospheric corrosion only of nonferrous metals and alloys.

Type B fluid is available with a rust inhibitor to prevent rusting of iron or steel surfaces. This type of silicone oil with rust inhibitor added is used as a relatively permanent lubricant at both high and low temperatures for instruments, clocks, and conveyor chains.

Type C Silicone Fluid. Type C silicone fluids are available in viscosity grades ranging from 100 to upward of 30,000 centistokes. These silicone fluids have properties unlike those of any other liquids, and they have therefore found a variety of applications including use as damping and hydraulic fluids, liquid dielectrics, mold release agents, waterproofing materials, and special-purpose lubricants. Only two viscosity grades of the Type C fluids that are of interest to lubrication engineers are shown in Table 18-8.

Type C silicone fluids are water white and inherently stable liquids which have flash points of 600°F or higher and pour points in the range of −58°F (−50°C). They show exceptionally little change in viscosity with temperature as shown by the data given in Table 18-8 and in Fig. 18-8.

Type C silicone fluid in the 100-centistoke viscosity grade is a useful hydraulic fluid. Comparative testing of silicone fluids of this type and a petroleum oil, meeting the specifications of AN-VV-O-366b, was done by the Naval Research Laboratory.[1] These experiments showed that there was no significant change (less than 2 per cent) in the viscosity of the silicone fluid after circulating at 1,500 psi continuously for 500 hr or 105,000 cycles. The petroleum oil used as a control retained less than 50 per cent of its original viscosity after 18,000 cycles at the same pressure. This silicone fluid has been operated successfully in an aircraft hydraulic system at pressures as high as 3,000 psi and at temperatures up to 200°C.

In these tests, however, it was found that the silicone fluid had very limited load-carrying capacity where both loaded sliding surfaces were ferrous. Where one or both of the bearing surfaces are nonferrous or can be replaced by suitable nonferrous metals, the silicone fluid gives excellent performance. For example, a steel thrust knuckle in a Vickers piston pump showed wear, but performance was entirely satisfactory when a bronze knuckle was used. In a Pesco gear pump, there was no wear on the hardened-steel gears but considerable wear on the cast-iron end bushings. Replacement with bronze bushings gave satisfactory performance.

The performance characteristics of this silicone fluid in unilaterally loaded journal bearings was also studied intensively by the Naval Research Laboratory.[2] It was found that this fluid was a good lubricant between certain metal combinations such as bronze on steel but poor between steel on steel. It was also found that heating the bearings in this silicone fluid at 150°C causes the formation of a silicone "lacquer" film on the steel surfaces which minimizes wear. The same kind of film was formed when bearings were run in carefully under light loads at elevated temperatures. After the silicone "lacquer" film was formed, loads as high as 5,500 psi could be applied to the journal bearings.

Petroleum Oils

8. Hydraulic oil A
9. Hydraulic oil B
10. Hydraulic oil C
11. Transformer oil

This same silicone fluid in the 1,000-centistoke grade is used as an antifoam additive for petroleum oils. It is effective in concentrations as low as 1 part to 100,000 parts of oil.[3]

High-viscosity Type C silicone fluids are being used in a torsional-vibration damping device on automotive and diesel-engine crankshafts.[4] Torsional vibrations of the shaft are damped out by the shear resistance of the silicone-oil film which separates a freely suspended flywheel encased in a hermetically sealed housing attached to the shaft.

SILICONE GREASES

Silicone greases are compounded from certain silicone oils and thickening agents that have a high order of heat stability. At the present time there are three types of silicone greases made to conform to the value given in Table 18-9.

Table 18-9. Test Data for Representative Silicone Greases

	Type I	Type II	Type III*
Worked penetration (ASTM D217-44T)	260–300	310–330	310–330
Flash point—determined on oil—(ASTM D92-46)	600°F	600°F	525°F
Dropping point (ASTM D566-42) not less than	415°F	415°F	415°F
Maximum per cent bleed at 300°F†	4.0	2.0	3.0
Maximum per cent evaporation at 300°F†	1.0	1.5	3.0

* Types II and III silicone grease can be supplied in different consistencies.
† Method AN-G-3a 24-hr test.

Volatility of Silicone Greases. Even though performance is the ultimate test of a lubricating grease, volatility can be measured and service life tentatively predicted from the measurements. In Table 18-10 the volatility of three silicone greases is compared to the volatility of high-temperature hydrocarbon greases.

After 40 hr exposure at 175°C, a crust had formed over the surface of the petroleum greases. The silicone greases were still soft and serviceable.

Type I Silicone Grease. Type I silicone grease, compounded of very finely divided carbon black and a silicone fluid of good lubricity, does not melt at temperatures above 500°F. It gradually thickens, however, at temperatures above 400°F, and more frequent lubrication is required at operating temperatures in excess of 300°F. Type I silicone grease is serviceable in antifriction bearings operating at speeds up to 4,000 rpm and at temperatures between −40 and 400°F.

Table 18-10. Percentage of Weight Lost after 40 hr at 347°F (175°C)

High-temperature petroleum greases			Silicone greases		
			Type I	Type II	Type III
58.3	39.3	34.8	4.2	3.3	4.6

In one test device, No. 212 ball bearings with bronze retainer rings were mounted on a shaft and spring loaded with 150 lb radial load. Both the shaft and bearings were enclosed in a housing that could be heated to any desired temperature. At a speed of 1,750 rpm, the average bearing life after one application of Type I silicone grease was 6,000 hr at 257°F (125°C) and 1,300 hours at 302°F (150°C).

Despite its more limited lubricity between steel bearing surfaces, Type I silicone grease has been used successfully in the bearings of the rotating spreader of an Economic stoker. The bearings in this spreader have steel retainers but are still serviceable after 2 years of nearly continuous operation at 300 to 350°F and at a speed of 900 rpm.

This silicone grease has proved to be especially useful for lubricating pumps handling hot fluids and for lubricating oven machinery and conveyor systems operating at high temperatures and in corrosive atmospheres. It is not satisfactory for lubricating high-speed bearings operating at speeds of more than 4,000 rpm.

Type II Silicone Grease. Type II silicone grease, compounded of a silicone fluid and a heat-stable metallic soap, is designed for the lubrication of antifriction bearings operating at speeds up to 20,000 rpm and at temperatures ranging from −40 to 350°F. Over this temperature range, it is practically nonvolatile and highly resistant to hardening. It will separate, however, at temperatures above 400°F. Test results summarized in Table 18-11 indicate that this silicone grease is an almost completely stable lubricant suitable for the permanent lubrication of ball bearings.

Table 18-11. Life Test on Type II Silicone Grease

Bearing temperature		1,750-rpm, tester life, hr	10,000-rpm, tester life, hr	1,750-rpm, electric-motor life, hr
Deg C	Deg F			
115	239	. .	.	5,600
125	257		6,500	3,800
150	302	2,600	2,600	
200	392	450		

Single Bearing, 1,750-*rpm Tester.* Tested in a No. 212 bearing with a bronze retainer ring mounted on a shaft spring loaded with 150 lb radial load in a heated enclosure, Type II silicone grease had a life of 2,600 hr at 302°F (150°C) and 450 hr at 392°F (200°C).

10,000-*rpm Tester.* The 10,000-rpm tester, shown in Fig. 18-9, consists of two standard No. 204 bearings in electrically heated housings and a belt-driven shaft. The shaft is driven at a speed of 10,000 rpm. Bearing failures are indicated by changes in torque, as measured by temperature rise in the bearings, and by changes in the hot and cold coasting time.

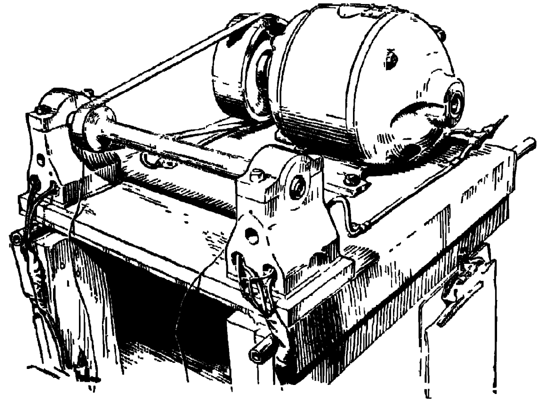

FIG. 18-9. Grease tester, 10,000 rpm using No. 204 bearings (housings are electrically heated).

Type II silicone grease failed after 2,600 hr at 302°F (150°C) and after 6,500 hr at 257°F (125°C) in this device. During these tests, however, the bearing temperature were inadvertently allowed to go above 200°C on two separate occasions. Once the temperature went up to 437°F (225°C) for 1 hr, and another time the temperature went up to 464°F (240°C) for 15 min. It is likely that the grease life was considerably shortened and probably the bearing metals were harmed by these runaway temperatures.

1,750-*rpm Silicone-insulated Motor.* To check these laboratory test results, this silicone grease was also tested in the bearings of silicone-insulated electric motors. The bearing temperatures are controlled by loading 7½-hp 1,750-rpm, 440-volt motors through belt-driven generators. The motors were insulated with inorganic materials bonded and impregnated with silicone resins and varnishes. They could therefore be operated at temperatures up to 590°F (310°C) by resistance to bring bearing temperatures up to 302°F (150°C).

A bearing lubricated with Type II silicone grease and operated at 239°F (115°C) failed after 5,600 hr in this test. A second bearing failed after 3,800 hr at 257°F (125°C).

From the data given in Table 18-11 it appears that Type II silicone grease gives long life to bearings operating at 239°F (115) to 257°F (125°C). At normal operating temperatures for electric motors, Type II silicone grease may be expected to give relatively permanent lubrication in sealed bearings. Such bearings are now being made for some of the leading manufacturers of electric motors.

Type III Silicone Grease. Type III grease is made of another silicone fluid thickened with a metallic soap. It is especially designed for low-temperature lubrication and is serviceable over a temperature range of −95 to 300°F and at speeds up to 20,000 rpm. Even though it is designed primarily for low-temperature applications, Type III has superior lubricating life at temperatures up to 300°F.

This grease is suitable for use as a permanent lubricant in sealed bearings subjected to extreme temperature variations and to outdoor weathering. For example, Type III is being used to lubricate the annular ball bearings in a wind-direction and velocity indicator which is exposed to the full range of ground temperatures and to the rain and weather. These bearings are relatively inaccessible so that relubrication is difficult. Type III was specified to meet these adverse operating conditions. It is also being used to lubricate certain aircraft bearings.

Other Silicone Greases. None of the following silicone greases is designed for lubricating bearings. They form heat-stable films which have good resistance to a variety of chemicals and sufficient lubricity to facilitate the turning of stopcocks, valves, and flowmeter bearings.

Stopcock Grease. The first silicone greases were designed for general laboratory use. One of these silicone greases effectively lubricates glass and ceramic stopcocks handling laboratory reagents including alkaline materials. Besides being nonvolatile, it does not harden or melt over a temperature range of −40 to over 200°C. This grease also facilitates the assembly and disassembly of rubber hosing and glass tubing and protects the rubber from oxidation and deterioration due to ozone.

High-vacuum Grease. High-vacuum grease is a special-purpose silicone lubricant which has properties similar to the silicone stopcock grease except that it is more cohesive and better suited to high-vacuum uses. It seals without channeling and effectively lubricates stopcocks and other ground-glass joints in vacuum systems operating at pressures of less than 10^{-6} mm Hg.

SILICONE LUBRICANT FOR PRESSURE-LUBRICATED VALVES AND FLOWMETERS

Another special-purpose silicone lubricant is used to lubricate and seal pressure-lubricated valves, automatic-control valves, and flowmeter bearings. It is resistant to a wide variety of chemicals and to relatively high temperatures. It is useful from −40 to 400°F and is resistant to steam.

This silicone valve lubricant is insoluble in water and unaffected by aqueous chemicals. It is noncorrosive to metals and useful against steam and many corrosive chemicals. It forms an effective seal in systems operating at high pressure or under vacuum.

SUMMARY

Silicone lubricants were developed to give effective lubrication under adverse conditions, including abnormally high- or low-temperature operation. Their function is to supplement rather than to displace petroleum oils and grease.

Silicone lubricants are especially useful in applications where both high and low temperatures are involved or where more nearly permanent lubrication is required. In general, the silicone oils and greases would seem to justify consideration in most applications to which petroleum oils and greases are not well suited.

MECHANICAL PACKINGS

BY F. C. THORN

Research Director, The Garlock Packing Company

AND J. R. BOYER

Consultant, E. I. du Pont de Nemours & Company

DEFINITIONS

The terminology of mechanical packings has never been accurately defined. The following definitions are believed to conform to accepted usage.

A *packing* is a nonrigid element designed for inclusion in the wall of a fluid container and designed to prevent or minimize leakage between the rigid parts of such a container.*

Packing (collective) is material in sheet, strip, or bulk form from which packings may be prepared.*

A *gasket* is a packing designed for inclusion between rigid parts of a fluid container in essentially stationary relationship.*

Gasketing (collective) is material in sheet, strip, or bulk form from which gaskets may be prepared.*

A *valve disk* is a specialized gasket composing the working face of a rigid valve and designed to improve its tightness when closed.*

(NOTE: In certain applications, as in the check valves of reciprocating pumps, the valve disk may compose the entire valve. More generally it is contained in a rigid *disk holder*.)

A *valve seat* is identical with a valve disk, except that it composes the stationary face of the valve. When a valve seat is employed, the disk itself may be wholly of rigid material.

A *sliding-contact packing* is designed for inclusion between rigid parts of a fluid container which are capable of relative motion. The packing is in stationary contact with one part and in sliding contact with the other part.

A *packing ring* is a sliding-contact packing designed for insertion into the annular space between two concentric cylinders in relative motion.

A *packing set* is a plurality of packing rings designed to fill such annular space which is generally adjustable for depth in order to bring pressure to bear on the packing set. The movable end wall is known as a "gland" and the annular space as a "stuffing box."

An inner cylindrical member to which a packing ring or set is affixed is a *piston*, and the packing ring or set used with it is a *piston ring* or *piston packing;* the annular space in which the packing is held is known as a *piston groove.*

An inner cylindrical member which has no packing affixed to it but which moves through a packing is known variously as a *rod*, *plunger*, *ram*, *valve-stem*, or *shaft*, according to size, function, and type of motion. Packings used with these are designated accordingly as *rod packings*, *plunger packings*, etc.

Cup packings, *hat* or *flange packings*, *U packings*, *V packings*, *O packings*, and *cones* are variants on the usual rectangular cross section of packing rings and, in the main, are self-descriptive terms. Although usually employed in sliding contact, any of these may be used as a gasket.

The term "seal" in the loose sense is applicable to anything that stops a leak and is therefore synonymous with "packing." In the restricted sense, the term is employed to designate one of two types of rotary shaft packing. A *radial seal* (sometimes, because of its frequent use in conjunction with bearings, known simply as an *oil seal*) is a hat or flange packing which is forced to contract against the shaft by the action of an internal spring. An *axial* or *shoulder seal* is a flexibly suspended packing ring making sliding contact on one of its flat faces with a similar ring which may be either rigidly or flexibly supported; one of the pair is affixed to the shaft and the other to the stationary part of the fluid container. Shafts packed with one or the other type of seal are frequently called "packless" but erroneously, since these are specialized packings.

---

* These definitions were accepted by ASTM Committee D-11, Subcommittee VI on Packings, and were published in the *ASTM Bull.*, May, 1940.

A *diaphragm* (in the packing sense) is a packing intended for inclusion between parts of a fluid container in limited relative motion and designed to absorb such motion by its own deformation.*†

The common forms of packing diaphragm are the *flat diaphragm* and the *cylindrical diaphragm*, or *bellows*. Either can function as a valve stem or piston packing.

Diaphragm sheet is sheet from which flat diaphragms may be cut.*

PACKING MATERIALS AND THEIR FABRICATION

The number of materials and fabricating methods employed by the packing industry is legion; space will permit only a brief reference.

Metals. Under certain conditions metals become sufficiently "nonrigid" to qualify as packings. Solid iron, copper, lead, etc., in the form of sheet, strip, wire, etc., are made into gaskets. Thin metal sheet is employed with asbestos paper, etc., in the manufacture of corrugated, jacketed, and spiral-wound gaskets and also for metal diaphragms. Braided wire or twisted foil are employed as rod packings. Wire is also used to strengthen asbestos yarns and, in the form of wire cloth, to reinforce rubber gasketing. The harder metals, such as cast iron, bronze, and babbitt, are used to construct axial-seal rings and segmental rod and piston packings; they are also used for such packing adjuncts as end rings and lantern rings. Steel is used for cases and springs. Comminuted metal is used in "plastic" packing.

The methods of manufacture are equally varied and include casting, rolling, forging, extrusion, wire drawing, cutting, stamping, spinning, twisting, wrapping, braiding, welding, brazing, machining, and pulverizing, none of which needs to be described here.

Carbon. Carbon in solid form (amorphous or graphitic) is machined into axial seals and segmental rod packings.

Natural Rubber. The first step in the conversion of natural rubber to packings is mastication followed by the incorporation of compounding ingredients. The most important compounding ingredient is sulfur, since this material combines with the rubber under the influence of heat and time to form the nonplastic "vulcanized" or "cured" rubber. With sulfur are added small quantities of organic accelerators to speed up vulcanization, zinc oxide to "activate" the accelerators, plasticizers to render the compound workable, and fillers to stiffen it to the desired extent. Prolonged vulcanization, in the presence of sufficient sulfur, also increases the stiffness of the compound, the end product being "hard rubber," or "ebonite."

Since vulcanization renders the compound nonworkable, it is postponed until late in the manufacturing operation. In the manufacture of packings, the unvulcanized rubber compound is treated in one of the following ways:

1. It is calendered into single- or multiple-ply sheets, which may be (*a*) vulcanized on drums with a fabric liner, which, after removal, leaves a fabric impression on the rubber sheet (this is the method employed in preparing common "red sheet"); (*b*) vulcanized in long hydraulic presses, giving a smooth surface; (*c*) rolled on a mandrel and vulcanized in steam in the course of which it coalesces to form a sleeve from which gaskets may be cut; (*d*) cut into blanks for molding.

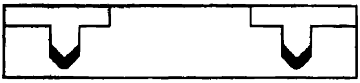
Molding involves the simultaneous application of pressure and heat to rubber compound contained in a confined space, in the course of which the compound assumes the shape of the space and is simultaneously vulcanized. The space, of the desired shape and size, is carved into a block of steel, which is usually separable into two or more parts at the conclusion of the molding operation to facilitate discharge of the molded article. The parting lines between these parts provide channels through which excess compound exudes in the form of a thin fin; this fin is afterwards removed, but enough of it generally remains to identify the product as a molded article. Four systems of molding are generally recognized:

---

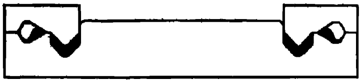
* These definitions were accepted by ASTM Committee D-11, Subcommittee VI on Packings, and were published in the *ASTM Bull.*, May, 1940.

† In the broad sense, hose, auto tires, and even balloons are flexible parts of fluid containers and hence "diaphragms." Perhaps a packing diaphragm is best defined as a "diaphragm that functions like a packing."

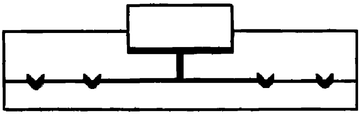
a. "Closed" molds (Fig. 19-1*a*), in which no particular provision has been made for the escape of that portion of the volume of the blank in excess of the mold volume when the mold parts are forced together by a hot hydraulic press. Since the use of a closed mold with a pure-rubber compound or other pure plastic requires that the blank be accurately weighed, the method is used more generally with fabric packings (see 2 below) in which internal voids are present to compensate for inaccuracies in blank preparation.



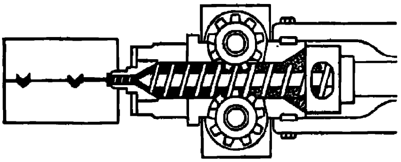
(a) Closed mold



(b) Open or flash mold



(c) Transfer mold



(d) Injection mold

FIG. 19-1. Types of rubber compound molds.

b. "Open" or "flash" molds (Fig. 19-1*b*), in which a flash groove has been provided to receive the excess material. These are generally employed with rubber compounds. Although a flash mold is also closed by a hot hydraulic press, the real pressure develops later when the compound heats up and tries to force the mold apart by virtue of its high rate of thermal expansion. Blanks for flash molding need conform only roughly to the shape and size of the mold.

c. "Transfer" molds, in which a cylindrical slug of rubber compound is forced into the surrounding mold cavities through tiny gate openings (Fig. 19-1*c*).

d. "Injection" molds (Fig. 19-1*d*), in which the mold cavities are recharged on each cycle by an independent screw extrusion machine. Injection molding is adapted only to small rubber or plastic parts in mass production, for which reason it has not found much application in the packing industry.

Molding is regularly employed for the preparation of packings of odd shapes not readily produced by other means; it may, however, be employed for the production of simple rings and disks where good finish or accuracy is wanted and where the number of pieces to be produced justifies the initial cost of the mold.

2. The unvulcanized rubber compound is applied to fabric by a calender, the operation being known as "frictioning" when the compound is driven into the interstices or as "skimming" when it is merely laid on the surface. Cloth-inserted gasketing or diaphragm sheet is built up by successive frictioning and skimming operations and vulcanized by method 1*a* or 1*b* above. Frictioned cloth may also be used in the preparation of slab and rolled packings or incorporated into molded packings.

3. The rubber compound may also be extruded by a worm extrusion machine as strip of any cross section which may be (*a*) cured in steam for the production of strip gasketing, (*b*) in the case of hollow cross sections, mounted on mandrels and cured as sleeves, or (*c*) cut into blanks for molding.

4. The rubber compound may also be made into solution in gasoline, which may be (*a*) applied to fabric by painting or dipping, the resultant coated cloth being used in exactly the same manner as frictioned cloth under 2; (*b*) applied to braid, metal foil, paper, etc., to fill the interstices; (*c*) used for joining the component parts of

molding blanks; (*d*) used for the preparation of compounds of higher filler content than is possible by dry mixing alone. In this category come compressed-asbestos sheet and rubber-bonded plastic packings whose manufacture is peculiar to the packing industry and deserves special description.

In the manufacture of compressed asbestos sheet, a small amount of rubber solution is placed in a dough mixer, and a large volume of asbestos fiber is kneaded into this, the operation requiring several hours. The resultant dough is fed to a special two-roll calender, known as a "sheeter" (Fig. 19-2), in which the larger roll is steam-heated while the smaller roll is water-cooled. The dough adheres to the hot roll in the form of a thin film and dries in the course of a single revolution, the solvent fumes being exhausted by appropriate ducts. At each revolution, the rolls are separated a little farther by worm gearing, thereby permitting a continuous build-up of dried sheet on the hot roll. When the correct thickness has been attained, the machine is stopped, and the finished sheet is removed as a large square, usually 10 ft on a side. This is press-cured or is calendered and then oven-cured.

The manufacture of rubber-bonded "plastic" rod packing is similar except that, in addition to fiber, it is customary to incorporate a variety of other materials such as flake graphite and particles of metal. The product is discharged from the mixer as a wet crumb and is either dried and sold as such or is fed to a worm extrusion machine from which it issues as a more or less coherent coil, which is sometimes further strengthened by the application of a braid of cotton or asbestos yarn. Other binders can be substituted for the rubber solution.

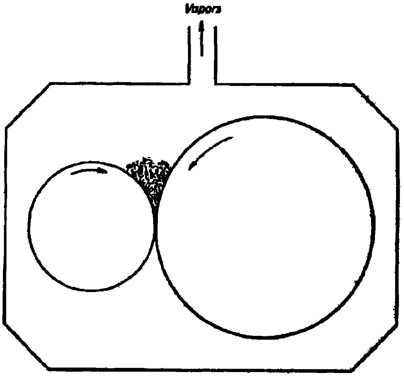


FIG. 19-2. Two-roll calender (known as "sheeter").

Gutta Percha and Balata. Gutta percha and balata are vegetable gums similar to natural rubber but, being incapable of vulcanization, have found little application in packings.

Synthetic Rubber—Styrene Type. Synthetic rubber—styrene type, known in Europe as buna S and in this country as GR-S, was the rubber available in the greatest quantities during the Second World War. It is a copolymer of two light hydrocarbons, butadiene and styrene, and resembles natural rubber closely. It employs the same compounding ingredients and fabrication methods and vulcanizes in about the same manner.

In general, GR-S compounds are physically weaker than natural-rubber equivalents but more resistant to the degrading effect of heat. For the latter reason, GR-S will probably continue to find important packing applications even if crude rubber is available in quantity.

Synthetic Rubber—Acrylonitrile Type. Synthetic rubber—acrylonitrile type, known in Europe as buna N and in this country under various proprietary names such as Perbunan, Hycar, Butaprene, and Chemigum, is similar to GR-S, substituting acrylonitrile for styrene in the molecule. It also is compounded, fabricated, and vulcanized like natural rubber but, being somewhat intractable, does not lend itself to all operations. The vulcanizates have fair physical and heat-resistant properties and are characterized by extraordinary resistance to the swelling action of ordinary petroleum oils. Toward benzol, carbon tetrachloride, etc., their superiority over natural rubber is not so pronounced and toward acetone is inferior.

Synthetic Rubber—Chloroprene Type. Synthetic rubber—chloroprene type, known as neoprene, is a polymer of chlor-butadiene. It likewise can be compounded, fabricated, and vulcanized like natural rubber but, unlike it, requires no sulfur to effect vulcanization. It is easier to handle than the acrylo-rubbers, and the products are stronger, although not quite so good in respect to oil or heat resistance.

Synthetic Rubber—Thio Types. Synthetic rubbers—thio types, marketed under the generic name "Thiokol," are believed to be organic polysulfides. They also can be compounded, fabricated, and vulcanized, although with more or less difficulty. Only metal oxides are needed to effect vulcanization. They are physically inferior to the other synthetics, more thermoplastic, less heat resistant, and characterized to varying degrees by strong onionlike odors. In resistance to the swelling action of benzol, chlorinated solvents, etc., they outrank the other synthetics.

Synthetic Rubber—Isobutylene Type. Synthetic rubber—isobutylene type, sold as butyl rubber, is a copolymer of isobutylene with isoprene, both hydrocarbons. Butyl is compounded, fabricated, and vulcanized like natural rubber; the vulcanizates are physically inferior and lacking in any appreciable solvent resistance but are characterized by appreciable resistance to many troublesome chemicals, such as nitric acid. Principal developed packing use is for acid gaskets.

Reclaimed Rubber. Reclaimed rubber, or more properly, reclaimed rubber compound, is vulcanized rubber or GR-S compound, mostly from used tires, which has been rendered plastic by drastic treatment with heat and plasticizers. Neither the combined sulfur nor the fillers are removed by this treatment, but the compound is rendered capable of processing and of revulcanizing with added sulfur. Reclaim is inferior to compounds made from new rubber or GR-S but is employed in certain types of packing, replacing new rubber wholly or in part.

Hydrocarbon Plastics. The hydrocarbon plastics include hydrocarbon polymers incapable of vulcanization. In this group are polystyrene (including high-styrene copolymers with butadiene), polyethylene (Polythene), and polyisobutylene (Vistanex). The last is processed like rubber, the first two by powder-molding or injection-molding. Owing to their thermoplasticity, the members of this group have only limited packing application in spite of their extraordinary resistance to corrosive chemicals such as nitric acid. Polyisobutylene confers high viscosity on mineral waxes, and such mixtures (Tervans) are used as binders in braids for high-temperature service, especially braided blue asbestos used for acid-pump packing.

Closely related to polyethylene is polymerized tetrafluorethylene, known as "Teflon." Although thermoplastic, the softening point of this material is high enough to permit its use as packing on all but the highest temperature, and its complete chemical inertness and resistance to all known solvents recommend it for chemical gasketing. Its principal drawbacks have been cost and manufacturing difficulties, since the only fabricating methods developed to date are sintering from powder, machining from the solid sheet or block, or incorporating, in granulated form, in a plastic.

Cellulose Plastics. The cellulose plastics, cellulose acetate, cellulose nitrate, ethyl cellulose (ethyl rubber), are thermoplastic, which has limited their packing application.

Vinyl Plastics. Vinyl plastics include polyvinyl chloride (Koroseal, Tygon), polyvinyl chloroacetate (Vinylite), polyvinyl butyral, polyvinylidene chloride (Saran), and polyvinyl alcohol (Resistoflex). Most of these can be plasticized to a rubber consistency and fabricated like rubber except for vulcanization. Although limited by thermoplasticity, they have found certain packing applications for cold service in the form of sheet, cut and extruded gaskets, and molded rod packings. The closely related acrylic plastics, familiar as Plexiglas, Lucite, etc., have, as far as is known, not been employed in packings.

Polyesters. The polyesters, which include the well-known "alkyd" varnishes, etc., include also a few rubberlike types (Agripol, Norepol, Paraplex, etc.) which have been employed in packings alone or in combination with synthetic rubbers.

Thermosetting Plastics. The thermosetting plastics include the phenolic, urea, melamine, etc., types. These become completely infusible and insoluble with heat and are acquiring increasing importance in packings, subject to the limitation that they are exceedingly hard. Principal forms are plastic masses containing large ratios of asbestos fiber which, after molding, are used for high-temperature valve disks, etc., and laminated slab built up from resin-coated paper or cloth. From the latter are cut high-temperature valve disks, piston rings for oil pumps, and axial-seal rings. Mixtures of phenolic resins with synthetic rubbers are known also.

Polysilicones. The polysilicones are the most recent and, in some respects, the most interesting of the plastics. They are available in forms ranging from thin liquids through rubberlike materials to hard resins. All are characterized by resistance to atmospheric oxidation and slow change of consistency with temperature. Up to date the high cost and physical weakness of the silicone rubber has somewhat limited its packing application, but these disadvantages will probably be overcome. During the Second World War silicone-rubber gaskets were used in searchlights and turbosuperchargers.

Polyamides. The polyamides include nylon which may have interesting packing possibilities. It has been available for too short a period to permit a proper evaluation.

Proteins are represented in the packing industry by gelatin which, in combination with glycerine, forms the binder in most paper gasketing.

Petroleum Derivatives. Petroleum derivatives such as mineral oils, waxes, and asphalts are used as plasticizers in rubber compounds and as binders in braided, plastic, and leather packings.

Coal Derivatives. Coal derivatives such as coal-tar oils, pitch, and cumarone resins are employed as rubber plasticizers.

Wood Derivatives. Wood derivatives such as rosin, pine tar, pine oil, and shellac are used as plasticizers in rubber compounds. Shellac is a binder in some metal-foil packings.

Simple Esters. Simple esters such as dibutyl phthalate, etc., are used as plasticizers for synthetic rubber and other synthetic polymers.

Fatty Oils and Waxes. Fatty oils and waxes and their derivatives are extensively used in the packing industry. Palm oil, cottonseed oil, stearic acid, and combinations of fatty oils with sulfur (factices) are used as rubber plasticizers. Tallow, raw, hydrogenated, and blown castor, soybean and fish oils, Japan wax, and carnauba wax are used in braided, plastic, and leather packings. Oxidized linseed oil applied to cloth (oilcloth) has been used for pump diaphragms. Glycerine is employed with gelatin in paper gasketing, with soap in certain braided packings, and alone as a surface treatment for rubber–asbestos rod packings.

Graphite. Graphite in powdered form is a common surface treatment for rod packings where it functions as a "surface leveler." Because of reputed corrosive effects, it has been partially replaced by talc and mica, which, however, are not so satisfactory as graphite in other respects.

Flax. Flax, in the form of braid, is the oldest and still perhaps the most widely used packing for water-pump rods. The property which flax has of swelling in water is important in this connection. Flax consists of, of course, the bast fibers of the flax plant from which the softer tissues have been removed by retting in water. It is received in this country in the form of tangled hanks which are combed in a special machine to separate the long fibers from the short fiber, or "tow." The long fibers are fed, end to end, into a drawing frame, and the resultant sliver is transferred to a spinning frame from which it issues as "long-line" flax roving. The tow, in turn, is put through a carding machine and spinning frame to form a second grade of flax roving. Both grades are used in the production of braided packings.

Although the braiding operation is employed in other industries, its use in the packing industry is sufficiently important to warrant a digression. Braiders are of three general types: (1) eight carrier, (2) multiple carrier, and (3) interlocking. The resultant braids are shown in Figs. 19-28*a*, *b*, and *c*. In the first two types, the spools carrying the yarns are in two groups, one group pursuing a clockwise orbit and the other a counterclockwise orbit, the orbits intersecting in the manner of a Maypole dance. In the eight-carrier braider, it is customary to produce the finished cross section in a single pass through the machine; the spools are wound with multiple-twisted yarns of sufficient diameter to accomplish this purpose. The product is square in cross section, but the squareness is usually accentuated by introducing straight yarns at four points in the circumference; these yarns are known as "corners" or "warps."

Other straight yarns are sometimes introduced into the center to control the finished diameter. These are known as "centers." The eight-carrier braider is usually employed in braiding flax yarn. Wherefore, this type of braid is sometimes known as a "flax braid."

Multiple-carrier braiders are available in 12, 16, 20, 24, or higher number of carriers. The product is normally polygonal in cross section, *viz.*, 6-sided for a 12-carrier braider, 8-sided for a 16-carrier braider, etc., but can be made to approximate a square cross section by the introduction of corner yarns at appropriate points. Centers are commonly used in multiple-carrier braids and may be large in relation to the cross section; also they are frequently of a dissimilar material, such as rubber or metal. Except where a center of large diameter is used, it is customary to build up the diameter of multiple braids by successive passes through the machine, the product being sometimes described as "braid-over-braid."

Interlocking braiders are basically similar to multiple-carrier braiders but have extra carriers which crisscross back and forth in the cross section, locking the structure into a solid mass. The advantage of interlocking braid is that the structure does not fall apart when the outer layer of yarns is worn through.

A braid is described by the number of braids, the number of carriers in each, yarns per carrier, size of yarn, presence or absence of corners and centers, and the "pitch," which is the axial length of braid for one complete revolution of any one carrier. The latter is controlled by gearing on the take-off capstan and is usually adjusted to equal the braid circumference, thereby giving all yarns except the corners and centers a uniform 45-deg angle to the braid axis; this gives a satisfactory balance between flexibility and stretch.

To be useful as a packing, a braid must generally be filled with some sort of binder. This binder is sometimes incorrectly described as a "lubricant," but its real function is to stop leakage through the body of the braid and to minimize leakage along the faces by acting as a surface leveler. In the case of square-braided flax, the binder is usually tallow or similar animal fat, or a mixture of same with paraffin, and is applied by soaking the finished braid in the molten binder, the excess being removed by draining or by passing the braid through a wiper or close-fitting die. Graphite is sometimes applied to the surface to assist the surface leveling.

Cotton Yarn. Cotton yarn, in the form of braid or woven cloth, is a common ingredient of packings for low-temperature service. The principal fabrics used in fabric-rubber packings are sheetings, drills, Osnaburgs, hose, belting, and tire and tent ducks. Raw cotton also is necessary in commercial asbestos yarn to carry the fiber through the carding process. Braided cotton is competitive with braided flax and braided asbestos.

Other Vegetable Fibers. Jute yarn is used to replace flax wholly or in part in braided packings; service life is believed to be somewhat lowered, but there is some saving in cost. As far as is known, no packing use is made of either domestic hemp, Manila hemp, or sisal, although flax or jute packings are sometimes erroneously referred to as "hemp." Ramie fiber makes a very durable packing which has been used as a stern-gland packing on vessels.

Rayon. Both the filament and staple types of viscose rayon have been used recently in braids with excellent results. Staple rayon also replaces cotton in asbestos-yarn mixes.

Other Synthetic Fibers. Both nylon and vinyl acetate (Vinyon) yarns are being employed experimentally in braided and fabric packings.

Asbestos. Two forms of asbestos are employed in packings. Chrysotile is a hydrated magnesium silicate found extensively in Canada, Russia, Rhodesia, and elsewhere. It appears to have been deposited from solution in cracks in the rock in the presence of considerable pressure and temperature, under which conditions it formed elongated crystals at right angles to the crack. The width of the crack therefore determines the fiber length. Originally, only the widest veins were saved, and the rock was carefully chipped away from these with hammers, the product being sold as "No. 1 crude" or "No. 2 crude," according to fiber length. This expensive process has been largely superseded by milling, wherein the entire product of the mine is crushed by successive passages through roll mills, each passage being followed by treatment on a vibrating screen equipped with a suction hood at the lower end, the liberated fiber being collected in cyclones. Milled fiber is rated, as shown in Table 19-1, according to the percentages remaining on standard shaking screens which were developed at the Canadian mines.

Table 19-1. Standard Classification Canadian Milled Asbestos Fiber

Group No.	Min residues, oz per lb, on			
	First screen	Second screen	Third screen	Pan
3 (spinning fibers)				
3F	7	7	1.5	0.5
3K	4	7	4	1
3R	2	8	4	2
3T	1	9	4	2
3Z	0	8	6	2
4 (shingle fibers)				
4H	0	5	8	3
4K	0	4	9	3
4M	0	4	8	4
4R	0	3	9	4
4T	0	2	10	4
4Z	0	1.5	9.5	5
5 (paper fibers)				
5D	0	0.5	10.5	5
5K	0	0	12	4
5M	0	0	11	5
5R	0	0	10	6

Grades such as 3F and 3K are only slightly inferior to the hand-picked crudes; they, however, are becoming increasingly scarce as the highest grade ore becomes exhausted and hence are reserved for the finest yarns. Grades 3R, 3T, and 3Z are employed for ordinary yarns. The No. 4 grades are designated as "shingle" grades. Various No. 4 grades are used in the manufacture of compressed-asbestos sheet and other fiber-containing rubber formulas, alone or in conjunction with No. 3 grades. The No. 5 grades are designated as "paper" stock and are employed in the manufacture of asbestos paper which is used as a packing itself and as a component of the various corrugated, jacketed, and spiral-wound metal gaskets.

The manufacture of asbestos yarn begins with a hammer mill designated variously as a "willow" or "opener." This breaks up the clots and eliminates sand either by air separation or screening. If crude fiber is used, it is first crushed on a Chile mill before being fed to the opener. The cleaned and opened fiber is then blended with a certain percentage of cotton in a device known as a "mixing picker." The purpose of the cotton is to carry the fiber through the subsequent carding operation, the longer fibers requiring the least cotton. A 100 per cent asbestos yarn can be made from selected crudes but is very expensive and is reserved for use in oxygen packings where the presence of vegetable fiber would be hazardous. Grade AAAA yarn contains less than 10 per cent cotton and is specified in special packings. Grade AAA (15 per cent cotton maximum) and Grade AA, or "underwriters" grade (20 per cent maximum), are used in packings; Grade A or "commercial" (25 per cent maximum) was used during the Second World War but is inferior.

Carding is common to most textile operations and consists in passage of the fiber over a drum lined with "card clothing," which resembles Turkish toweling but is made of wire. The action of the drum and adjacent rolls is to spread the fiber out into a film, or "lap," of almost gossamer fineness. This is broken up into bands, each of which passes between rubbing leathers to issue as a continuous but weak "roving." The rovings are fed to a spinning frame which imparts a twist. The resultant "single" yarn is plied up on a similar but larger machine, and at the same time one or more fine wires (copper or brass) may be twisted into it to give added strength. Yarn is identified by some such designation as "1021" which implies that the single yarn is "10 cut," *i.e.*, ten 100-yard lengths to the pound. There are two plies and one wire.

The preparation of cloth from yarn is a simple weaving operation, common to all branches of textile manufacture. Braiding follows the methods described under flax. Asbestos braids are quite generally saturated with a soft binder such as petrolatum, and inasmuch as this results in a binder content too great for certain services, alternative methods are employed wherein the yarn is pretreated before braiding with controlled amounts of binder, or treated and untreated yarns are mixed in the cross section. Graphite is quite generally applied as a surface leveler and may, in addition, be incorporated throughout the cross section, giving what is known as a "graphited-throughout" construction which is believed to have advantages for certain services.

Blue or Crocidolite Asbestos. Blue or crocidolite asbestos is found principally in the Union of South Africa. Chemically it is an amphibole, with a high iron content to which it owes its blue color and much less water of hydration than chrysotile. It appears on the market as fiberized crude, as twisted rovings for calking joints, and as spun yarns and cloth, generally made without cotton. The fiber is harsher than chrysotile and the yarn somewhat uneven and bulky. However, it is much more resistant than crysotile to the action of strong minerals acids and alkalies and, hence, preferred for chemical applications.

Glass Fiber. Glass fiber is a modern product which has been employed in packings in the form of felt, yarn, cloth, and braid. Since it is chemically resistant, it has competed somewhat with blue asbestos. Although very strong in tension, glass fiber is somewhat inelastic and tends to crumble under tightening loads. Also, in the form of braid, it is somewhat lacking in power to retain binder. As the art of fiber making improves, glass fiber will become increasingly important in packings.

Wool in the Form of Felt. Wool in the form of felt has been widely used as dust seals and also in the manufacture of oil seals, using a synthetic-rubber binder, or as a gasket with a surface coating of synthetic rubber.

Paper. Paper from waste rope or kraft pulp, and purposely made porous, is a widely used gasket material. It is saturated with glycerin–gelatin or with a natural- or synthetic-rubber solution. By the incorporation of granulated cork in the beater, the porosity and compressibility are further increased. Asbestos paper has been mentioned.

Cork. Cork, in the form of the cork stopper, constitutes one of the most widely used "gaskets." In the form of corkboard, made from cork granules with a binder of glue, synthetic rubber, or plastic, it is used in bottle caps and for many other gasketing applications.

Leather. Leather is one of the oldest packing materials and is still widely used, especially for heavy-duty hydraulic rams and plungers. Small, cheap cup packings, such as those used in Flit guns, are often made from leather shoe trimmings.

For hydraulic leathers all tannages are used, but the favorite, perhaps, is a combination of vegetable and chrome tannage. Blanks are cooked in wax and afterwards hot pressed to cup or V form along the lines of rubber molding, except that there is no vulcanization, but the mold is cooled before discharging the product to set the wax and fix the shape of the article. Binders other than wax are also employed. Thin sheepskin leather is employed as a diaphragm, especially for gas meters.

Wood. Wood in solid form has been employed as a gasket material, this in addition to its use as a source of wood pulp for paper and of ground wood as a filler for rubber or plastics.

GASKETS

A gasket will stop leakage if it is exerting against the confining members a unit compressive force greater than that of the fluid pressure. Mere contact is not enough, and adhesion cannot normally be depended upon. It follows that any gasketed joint should embody means for putting the gasket under this state of compression and keeping it there for the expected life of the gasket between retightenings.

The most widely used type of joint is the flange joint, shown in various modifications in Fig. 19-3. In this joint, the bolts or other tightening means have the following functions to perform:

1. Support stresses in the container walls caused by the fluid load acting across an area equal to the inside area of the gasket.
2. Support any additional stresses in the container walls caused by gravity, misalignment, or thermal expansion and contraction. These, however, should be eliminated as far as possible by suitable design.
3. Develop a unit gasket load over all portions of the gasket area equal to the

fluid pressure times a safety factor* sufficient to take care of natural relaxation of the gasket during the interval between tightenings.†

4. Develop additional load over those portions of the gasket area first contacted to depress these sufficiently to permit development of the safe unit gasket load over the rest of the area. The necessity for this arises from irregularities in the gasket or in the flange faces. Irregularities in the flange faces may be present originally or induced by flange deflection under bolting load.‡

Under Materials were mentioned a large number of gasket types suitable for the bolted flange joint. Some of the more important ones are summarized in Table 19-2. Although the number is large, they are by no means equally important. It seems probable that plain-rubber or GR-S gaskets pack 90 per cent of all flange joints operating against gases, water, or aqueous solutions below 220°F. Vegetable-fiber paper and oil-resistant synthetics occupy a similar role against oils and solvents below 220°F, and compressed-asbestos sheet a similar role for all services between 220 and 500°F.

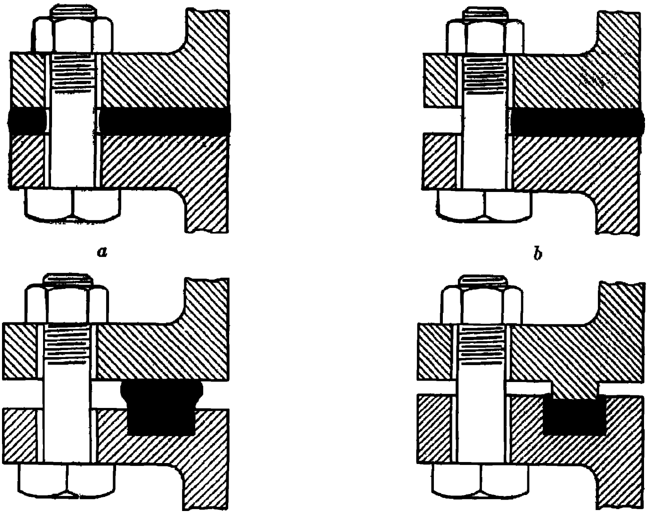

Fig. 19-3. Types of flange joints.

---

* This safety factor is known as the "contact-pressure ratio" and was designated by the British Institution of Mechanical Engineers in their First Report of the Pipe Flange Research Committee, 1936, as e_3. A somewhat similar factor m appears in the ASME formulas for Bolted Flanges (ASME Code for Unfired Pressure Vessels, 1943, Section UA-20) except that m is 0.5 lower than e_3 owing to the assumption in the American formulas that fluid load is effective to the middle of the gasket area instead of to its inside edge.

† The amount of this relaxation is usually underestimated. For instance, a high-grade synthetic-rubber gasket in $\frac{1}{16}$-in. thickness will lose 60 per cent of an initial 2,000-psi gasket load between smooth flanges after 20 hr at 212°F. It follows that e_3 must be at least 2.5 (m at least 2.0) if the gasket is to survive even this mild service exposure. Thick gaskets poorly confined, and higher temperatures further increase the rate of relaxation and the consequent need for a high safety factor unless frequent retightening is resorted to. Substitution of other types, such as compressed-asbestos sheet, reduces but by no means eliminates relaxation. On the other hand, thinner gaskets (where flange accuracy permits), roughened flange surfaces, and long stretchy bolts capable of exerting a "follow-up" effect reduce relaxation and reduce the need for high safety factors or frequent retightening.

‡ The ASME formulas recognize the need for a minimum gasket load y which is defined as the "gasket or joint contact-surface unit seating load." Unfortunately, this is treated as a property of the gasket, whereas, at least for soft gasketing, it is almost wholly a measure of the inaccuracy of the joint and will vary with each joint.

The need for flange accuracy will become apparent when it is realized that the total compressibility of a $\frac{1}{8}$-in. compressed-asbestos gasket is about 0.020 in., *i.e.*, if the cumulative deviation of the two [illegible]

[illegible]

a l[illegible]r extent to even the more compressible gasket types.

Among the fabric-inserted gaskets, the cotton-inserted type is preferred to plain rubber by some users because the material holds its shape better while being cut—the insertion has no other function. Metal-wire insertion, however, has some merit in restraining lateral flow on gaskets subjected to heavy bolting loads as in hydraulic lines. Flat asbestos-fabric gaskets have been largely superseded by compressed-asbestos sheet, but folded asbestos-fabric gaskets are still widely used where a gasket more compressible than compressed-asbestos sheet and involving less waste in manufacture is needed. Such applications include boiler handholes and manholes, large reaction vessels, column stills, etc.

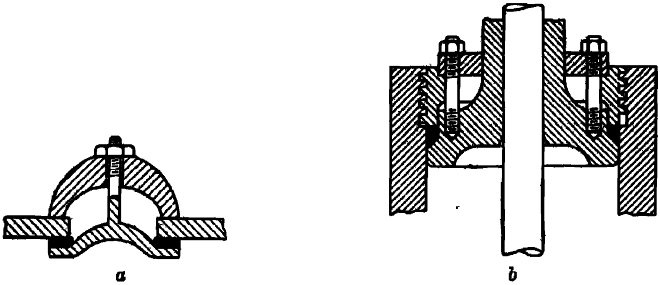

Fig. 19-4. Self-tightening flange joints.

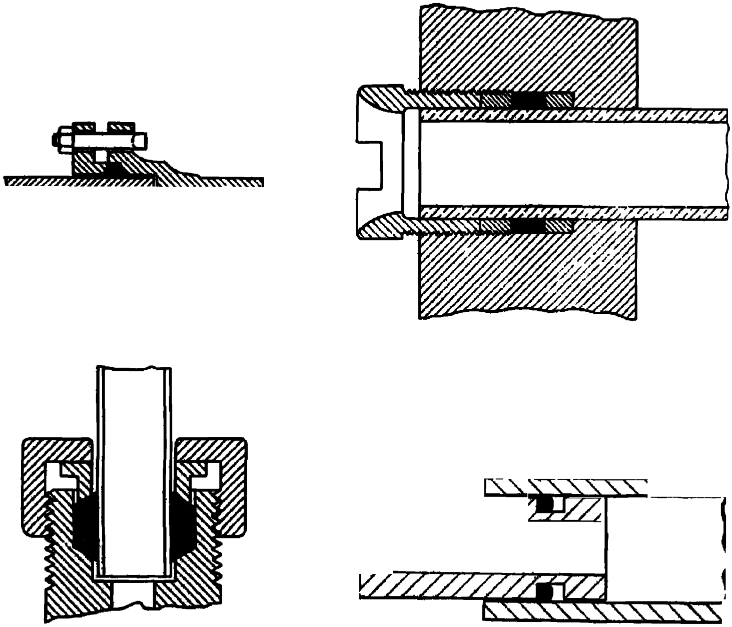

Fig. 19-5. Concentric joints.

Leather gaskets are tough and are often used where surfaces rotate at the time of closing, under which conditions a rubber gasket would be injured. Braided-asbestos gaskets, are used for the same services as asbestos-fabric gaskets, especially in locations such as furnace doors where destruction of the rubber binder by oxidation would cause a fabric gasket to open at the seams. Silicone rubber in conjunction with asbestos braid makes an interesting product for such applications. Braided flax has been used for hatch gaskets on merchant vessels but is probably inferior to rubber.

Metal gaskets, because of their cost, have largely been limited to severe temperature and pressure applications. Polyvinyl chloride and Teflon are employed principally where their chemical inertness is of value.

Flange joints can be made so that they are self-tightening under fluid pressure, as in the case of the boiler handhole (Fig. 19-4*a*) and valve-bonnet joints (Fig. 19-4*b*). Since any danger of failure through relaxation is avoided with these designs, it is rather surprising that they are not more widely used.

In another class of gasketed joint, the surfaces to be packed are concentric and parallel. These joints, except for absence of relative motion, correspond exactly to sliding-contact joints and have the great advantage that the axial spacing of the parts to be joined need not be determined in advance. Examples are the cast-iron pipe joint (Fig. 19-5*a*), the condenser tube-sheet ferrule (Fig. 19-5*b*), the gauge-glass gasket (Fig. 19-5*c*), and the "O-ring" gasket (Fig. 19-5*d*). Except for the last type, which is self-tightening at all loads provided the ring has been given an initial squeeze, concentric gaskets require the application of bolt load equal to the fluid load times an appropriate safety factor to take care of gasket relaxation. Bolts, however, are not required to support stresses in the container walls, for which independent provision must be made. Concentric gaskets are usually either plain rubber or rolled fabric.

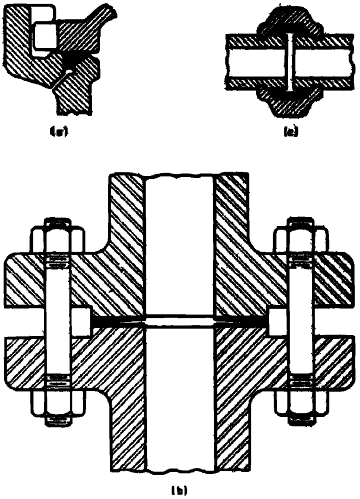

FIG. 19-6. Types of gasket joints.

In still another type of gasketed joint, the gaskets are made cup-shaped to admit the fluid pressure to the interior and thereby render the gasket self-tightening. Such joints can be of either the flange or concentric types. The vulcanizer joint (Fig. 19-6*a*), hollow metal gasket joint (Fig. 19-6*b*), and pipe joint (Fig. 19-6*c*) belong to the former category. It has been noted above that the O-ring design, although not cup-shaped, is also self-tightening. All self-tightening gaskets, to be effective, must be carefully designed and molded to extreme accuracy.

Since a gasket, except a cup gasket, is exposed only on the edge to the fluid being packed, its problems are primarily mechanical rather than chemical. It is possible, however, for a gasket to fail by chemical attack. In prescribing gaskets for various fluids, therefore, it is necessary to take both mechanical and chemical conditions into account. A list of recommendations for flange gasketing for various services is given in Tables 19-3 and 19-4. Similar recommendations for the various "specialty" joints (Figs. 19-5 and 19-6) can, in some instances, be secured from the packing manufacturer.

VALVE DISKS AND VALVE SEATS

Pump Valves. The standard check valve of a reciprocating pump (Fig. 19-7*a*) consists of a bronze grid which screws into the valve deck, a center post, and a rubber disk which rides up and down on the post under the influence of the escaping water and a helical spring. The design is not very good, since the rubber valve tends to take the imprint of the grid, and when the valve later rotates slightly, it cannot seat and must be refaced. Better results are secured by recessed ribs or an overhead suspension—if the soft valve cannot support itself over the larger opening, it can be contained in a metal disk holder (Fig. 19-7*b*).

Other common faults of the grid arrangement are (1) that the valve tends occasionally to be dragged sideways by the escaping water and wears the center hole elliptical. In the absence of a metal disk holder, as in Fig. 19-7*b*, this can be partially corrected by purchasing valve disks with a molded-in bushing of metal or other material; (2) that the edges of the ribs are frequently ground with a razorlike edge which cuts the disk—these should be filed off before use.

Rubber pump valves range in hardness from pure gum (used for condenser vacuum pumps) to ebonite (used for boiler-feed and other hot-water pumps). Other materials used are leather, laminated phenolic resin, and even metal, in the form of superimposed thin stampings (Fig. 19-7*c*). Similar valves used in reciprocating air compressors are almost invariably of polished sheet steel, although seme small compressors such as those used in garages have rubber check valves.

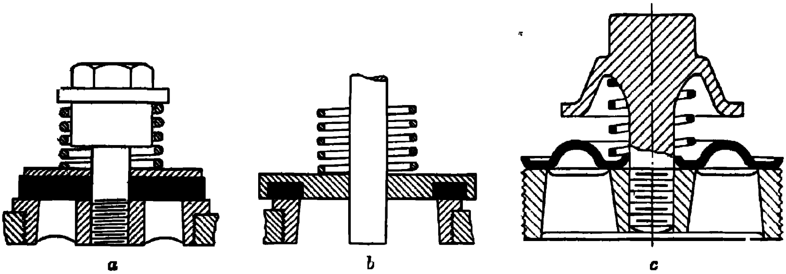

FIG. 19-7. Pump valves.
